$$\begin{aligned} \text{odds}(\text{control}) &= \frac{\pi(x_1=0)}{1 - \pi(x_1=0)} \\ &= \exp\left(\alpha_0 + \sum_{i \geq 2} \beta_i x_i\right) \\ \text{odds}(\text{active}) &= \frac{\pi(x_1=1)}{1 - \pi(x_1=1)} \\ &= \exp\left(\alpha_0 + \beta_1 + \sum_{i \geq 2} \beta_i x_i\right) \end{aligned}$$

Hence, the odds ratio of the active group relative to the control group is odds (active)/odds (control) = $\exp(\beta_1)$. This implies that β_1 is a measure of the odds ratio. The $1 - \alpha\%$ confidence interval for $\exp(\beta_1)$ can be obtained in a conventional way as follows: $\exp(\hat{\beta}_1 \pm \alpha/z\text{SE}(\hat{\beta}_1))$.

- Based on the discussion in point (g), the odds ratio can be generalized for any covariate i , which is equal to $\exp(\beta_i)$.
- Logistic regression is analogous to analysis of covariance. Analysis of covariance is for the comparison of mean responses adjusted for covariate(s), while logistic regression is for the comparison of proportion responses adjusted for covariate(s).

Group 5

Cox Proportional Hazards Analysis

Study Design: Parallel group design.

Model Assumptions: Independence.

Number of Observations per Patient for PD Parameter: 1.

Purpose: To determine and compare the survival time between the PD parameter and explanatory variable(s).

Statistical Model: $h(t) = \lambda(t) \exp(\sum_i \beta_i x_i)$.

Hypothesis Testing for one correlation β_i : $H_0: \beta_i = 0$ vs. $H_a: \beta_i \neq 0$

Test Statistic for β_i : $\chi_w^2 = \left(\frac{\hat{\beta}_i}{\text{SE}(\hat{\beta}_i)} \right)^2$

Rejection Region for β_i at α level: $\chi_w^2 > \chi_{1, 1 - \alpha/2^2}$.

Hypothesis Testing for a Subset of Model Parameters β_q : $H_0: q = 0$ vs. $H_a: q \neq 0$

Test Statistic for β_q : $X_w^2 = \mathbf{b}_q' (\text{COV}(\mathbf{b}_q))^{-1} \mathbf{b}_q$.

Rejection Region for β_q at α level: $\chi_w^2 > \chi_q, 1 - \alpha/2^2$.

Related SAS Procedure: PROC PHREG.

Description of and Notes on the Method:

- In this method, there are two responses for the PD parameter, with 0 indicating the non-occurrence of the event of interest and 1 indicating non-occurrence.

- b. The notations in the model are defined as follows:
- x_1 = treatment effect (in the case of two treatments, we may define $x_1 = 1$ for active drug and $x_1 = 0$ for placebo)
 - $x_2, \dots, x_k = k - 1$ other explanatory variables ($k \geq 1$), which can be continuous or discrete
 - $h(t)$ = hazard function at time t associated with $\mathbf{x} = (x_1, x_2, \dots, x_k)$
 - $\lambda(t)$ = unspecified initial hazard function at time t
 - β_i = correlation (slope) between $\pi(\mathbf{x})$ and x_i
 - $\boldsymbol{\beta}_q = (\beta_1, \beta_2, \dots, \beta_q)'$ is a subset of $\boldsymbol{\beta} = (\beta_1, \beta_2, \dots, \beta_k)'$
 - $\mathbf{b}_q = (b_1, b_2, \dots, b_q)'$ is an estimate of $\boldsymbol{\beta}_q = (\beta_1, \beta_2, \dots, \beta_q)'$
 - $\text{COV}(\mathbf{b}_q)$ = variance-covariance matrix for $\mathbf{b}_q$
 - $\text{SE}(\boldsymbol{\beta}_i)$ = standard error of estimate of $\boldsymbol{\beta}_i$
- c. The test statistic, called the Wald statistic, was discussed under "Group 4, Logistic Regression."
- d. The log-likelihood test is also common for this analysis, in addition to the Wald chi-square test.
- e. We should first test β_i for any $i \geq 2$ to determine which covariates are correlated with the hazard function, then we test β_1 between the two treatment groups.
- f. Cox proportional hazards analysis is analogous to logistic regression, where logistic regression is dealing with the proportion of responses for treatment groups, with adjustment for covariate(s), and Cox proportional hazards model is dealing with survival time responses for treatment groups, with adjustment for covariate(s). On the other hand, Cox proportional hazards analysis is also similar to the log-rank test because both tests are used for analyzing survival time. The log-rank test, however, does not take into account any covariate, whereas the Cox proportional hazards analysis does.
- g. It can be shown that $\exp(\hat{\beta}_i)$ is an estimated risk ratio for covariate i and is independent of time and other covariates.

CONCLUSION

Because there are potentially many other different cases that may arise in a clinical setting, this entry only a purpose

of covering mostly known cases and the most commonly used statistical methodologies.

Abstract

This entry discusses several univariate statistical methods that are used mostly for Phase III clinical studies for considering one independent and one dependent variable.

Keywords: Covariate; Pharmacodynamics; Univariate.

INTRODUCTION

In this entry, we will discuss several univariate statistical methods that are used mostly for Phase III clinical studies for considering one independent and one dependent variable. This entry will serve as a review for biostatisticians and as a utility tool for non-statisticians. In the following discussions, we will specify the underlying conditions (including study design, model assumptions, and number of data points per patient) that apply to each method. Note that “explanatory variable” refers to treatment (or dosage level). “Response variable” refers to the PD parameter, and we will consider the clinical trials with a single, primary PD parameter.

We will divide clinical trials into four groups according to the type of PD parameter and the number and type of explanatory variables. Table 1 displays the summary of these four groups. The statistical methods for the groups in Table 1 may apply to single-center studies or to multi-center studies with no consideration of a “center” effect. However, in general it is advised that an investigation of the center effect as well as the center-by-treatment effect be performed *before* data from all centers in a multi-center clinical study are combined and analyzed. Statistical methods for considering the center effect and/or other effects, such as demographic data and baseline evaluations, are discussed in the entry titled *Pharmacodynamics with Covariates*.

A discussion of each statistical method will cover purpose, statistical model, hypothesis testing, test statistic, rejection region, confidence interval, two-sided p -value, description of and notes on the method, and any related SAS procedure. (SAS, the most popular statistical software package, is also accepted by the Food and Drug Administration as one of the standard packages.)

The statistical methods discussed for each group are listed in Table 2.

STATISTICAL METHODS

Group 1

Two-Sample t-Test

Study Design: Parallel group design (or completely randomized design).

Model Assumptions: Normal distribution, independence, and equal variance.

Number of Observations per Patient for PD parameter: 1.

Purpose: To compare the equality of two treatment means.

Hypothesis Testing: $H_0: \mu_1 = \mu_2$ vs. $H_a: \mu_1 \neq \mu_2$

$$\text{Test Statistic: } T_0 = \frac{(\bar{Y}_1 - \bar{Y}_2)}{S \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

Rejection Region at α Level: $|T_0| > t_{(n_1 + n_2 - 2), (1 - \alpha/2)}$

100(1 - α)% Confidence Interval:

$$\bar{Y}_1 - \bar{Y}_2 \pm t_{(n_1 + n_2 - 2), (1 - \alpha/2)} \left(S \sqrt{\frac{1}{n_1} + \frac{1}{n_2}} \right)$$

Two-Sided p Value: $2 \times (1 - \text{PROBT}(|T_0|, n_1 + n_2 - 2))$.

Related SAS PROC Procedure: PROC TTEST.

Description of and Notes on the Method:

- Each patient is assigned to one of the two treatment groups and contributes only one observation to the entire data set.
- The data collected from the two treatment groups are independent because they are from different patients.
- μ_1, μ_2 represent the unknown population means for treatment groups 1 and 2, respectively.

Table 1 Classification for Model Grouping

Group	PD variable		Treatment variable No. of values
	Continuous (C) vs. discrete (D)	No. of values ^a	
1	C	—	2
2	C	—	2 or more
3	D	2	2
4	D	2 or more	2 or more

^aWhen “C” is specified, this column is not needed.

Table 2 Statistical Methods for Each Group

Group	Statistical methods
1	Two-sample <i>t</i> -test Paired <i>t</i> -test Wilcoxon's rank-sum test Wilcoxon's signed-rank test
2	One-way analysis of variance Kruskal-Wallis test Log-rank test
3	Fisher exact test McNeMar's test
4	Chi-square test

- d. $\bar{Y}_1, \bar{Y}_2$ are the sample means for treatment groups 1 and 2, respectively; n_1 and n_2 are the sample sizes for treatment groups 1 and 2, respectively.
- e. S is the pooled standard deviation, calculated via $\sqrt{\frac{(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2}{n_1 + n_2 - 2}}$ where S_1^2 and S_2^2 are the variances of treatment groups 1 and 2, respectively.
- f. PROBT (x , d.f.) expressed in the two-sided p value is the cumulative probability function for the t distribution in SAS.
- g. $t_{(n_1 + n_2 - 2), (1 - \alpha/2)}$ is the numerical value at which the cumulative probability is $1 - \alpha/2$ under a t distribution with $n_1 + n_2 - 2$ degrees of freedom.
- h. The hypothesis testing can be modified from a two-sided test to a one-sided test, depending on the study objective.
- i. The p -value of a one-sided test can be obtained by halving the p -value of the two-sided test if the test statistic is positive and the alternative hypothesis is a right-tailed test ($H_a: \mu_1 > \mu_2$), or the test statistic is negative and the alternative hypothesis is a left-tailed test ($H_a: \mu_1 < \mu_2$).
- j. The rejection region for the right-tailed test ($H_a: \mu_1 > \mu_2$) is $T_0 > t_{(n_1 + n_2 - 2), (1 - \alpha)}$; the rejection region for the left-tailed test ($H_a: \mu_1 < \mu_2$) is $T_0 < t_{(n_1 + n_2 - 2), (\alpha)}$.
- k. A preliminary two-sided F -test on equal variances of the two treatment groups is highly suggested. When the null hypothesis of equal variance is rejected, the

test statistic listed earlier may not be applied. Instead, you may employ an approximate t -test statistic of the form $T_0 = \frac{(\bar{Y}_1 - \bar{Y}_2)}{\sqrt{\frac{S_1^2}{n_1} + \frac{S_2^2}{n_2}}}$ with the approximate degrees of freedom^[1]

$$\text{d.f.} = \frac{\left(\frac{S_1^2}{n_1} + \frac{S_2^2}{n_2} \right)^2}{\left(\frac{\left(\frac{S_1^2}{n_1} \right)^2}{(n_1 - 1)} \right) + \left(\frac{\left(\frac{S_2^2}{n_2} \right)^2}{(n_2 - 1)} \right)}$$

Paired t-Test

Study Design: Parallel group design.

Model Assumptions: Normal distribution, dependence.

Number of Observations per Patient for PD Parameter: 2.

Purpose: To compare the equality of two observations within the same treatment group.

Hypothesis Testing: $H_0: \mu_d = 0$ vs. $H_a: \mu_d \neq 0$

$$\text{Test Statistic: } T_0 = \frac{\bar{Y}_d}{\frac{S_d}{\sqrt{n}}}$$

Rejection Region at α Level: $|T_0| > t_{(n-1), (1-\alpha/2)}$

100(1 - α)% Confidence Interval: $\bar{Y}_d \pm t_{(n-1), (1-\alpha/2)} S_d / \sqrt{n}$

Two-Sided p Value: $2 \times (1 - \text{PROBT}(|T_0|, n - 1))$.

Related SAS Procedure: PROC MEANS.

Description of and Notes on the Method:

- a. This test, in general, applies to the comparison of two readings under two conditions for the same treatment from the same sample of patients. The two readings are dependent and highly correlated since they are obtained from the same patient sample. Normally, this test is more useful for within-treatment comparison than for between-treatments comparison. Two examples of such an application are baseline vs. posttreatment and two posttreatment results at two different time points.
- b. One reason why this paired t -test is not an ideal test for comparing two treatments if the two evaluations are collected under two different treatments for the same patients is that one treatment is always administered before (or after) the other, so the treatment effect may be confounded with the order/time effect. It is more appropriate to design such a study in a crossover fashion, so every patient can receive both treatments. (Please refer to the entry on *Pharmacodynamics with Covariates* for a detailed discussion of crossover design.)

- c. μ_d = population mean of paired difference
 - $\bar{Y}_d$ = sample mean of μ_d
 - n = number of pairs
- d. Patients with only one observation are removed from the analysis.
- e. A one-sided paired test can also be employed in a similar way to a two-sample t -test.

Wilcoxon's Rank-Sum Test

Study Design: Parallel group design.

Model Assumptions: Independence.

Number of Observations per Patient for PD Parameter: 1.

Purpose: To compare the equality of two treatment medians.

Hypothesis Testing: $H_0 : M_1 = M_2$ vs. $H_a : M_1 \neq M_2$

$$\text{Test Statistic: } Z_0 = \frac{\text{sign}\left(R_1 - \frac{n_1(N+1)}{2} - 0.5\right)}{\sqrt{\frac{n_1 n_2}{12} \left(N+1 - \frac{\sum_i m_i(m_i^2 - 1)}{N(N-1)}\right)}}$$

Rejection Region at α Level: $|Z_0| > Z_{1-\alpha/2}$

Two-Sided p -Value: $2 \times (1 - \text{PROBNORM}(|Z_0|))$.

Related SAS Procedure: PROC NPARIWAY.

Description of and Notes on the Method:

- a. This parallels the two-sample t -test, with the following two major differences:
 - i. Normal distribution of the PD parameter is not required.
 - ii. Comparison is based on the median, not on the mean.
- b. A preliminary test of normality can be performed to determine whether the data are normally distributed. A Shapiro-Wilk or Kolmogorov can be used, which is available in the PROC UNIVARIATE procedure of SAS.^[2]
- c. In order to employ this non-parametric test, the data from both treatment groups are first ranked from lowest to highest. The average rank is assigned to tied values if applicable.
- d. R_1 represents sum of ranks associated with treatment 1, n_1 and n_2 represent the sample size for treatments 1 and 2, respectively. $N = n_1 + n_2$.
- e. m_i represents the number of ties for the i th value that has ties.
- f. $\text{sign}(|y| - a) = \begin{cases} y - a & \text{if } y > a \\ -(|y| - a) & \text{if } y < a \end{cases}$
- g. $\text{PROBNORM}(x)$ is the cumulative probability function at x for the standard normal distribution in

SAS, and $Z_{1-\alpha/2}$ is a numerical value at which the cumulative probability is $1 - \alpha/2$ under a standard normal curve.

- h. "0.5" in the test statistic is known as "correction for continuity." It is not always necessary to include it in the test statistic. When it is not used, the numerator of the test statistic can be simplified as $R_1 - n_1(N+1)/2$ without the absolute-value sign.
- i. The Wilcoxon rank-sum test is shown to be equivalent to another nonparametric test for two independent samples, i.e., the Mann-Whitney U test, when the continuity for correction is not used^[3] (Ref. [4], p. 406).
- j. A one-sided Z -test may be performed in the same manner as for a t -test.
- k. For $n > 30$, we may feel free to use a two-sample t -test instead of this nonparametric test if the data are symmetric, based on the central limit theorem that the sample mean tends to be normally distributed for large sample sizes (> 30) regardless of the underlying distribution of the data.
- l. Another approximation test procedure to employ is a two-sample t -test with the ranked data.^[5]

Wilcoxon's Signed-Rank Test

Study Design: Parallel group design.

Model Assumptions: Dependence.

Number of Observations per Patient for PD parameter: 2.

Purpose: To compare the median of two observations within the same treatment group.

Hypothesis Testing: $H_0 : M_d = 0$ vs. $H_a : M_d \neq 0$

Test Statistic:

$$T_0 = \frac{\left(\frac{R^+ - R^-}{2}\right)\sqrt{n-1}}{\left(\frac{n^2(n+1)(2n+1)}{24} - \frac{n \sum_i (m_i^3 - m_i)}{48}\right) - \left(\frac{R^+ - R^-}{2}\right)^2}$$

for small sample size,

$$Z_0 = \frac{\text{sign}\left(\min\{R^+, R^-\} - \frac{n(n+1)}{4} - 0.5\right)}{\sqrt{\frac{n(n+1)(2n+1)}{24} - \frac{\sum_i (m_i^3 - m_i)}{48}}}$$

for large sample size.

Rejection Region at α Level: $|T| > T_{(n-1), (1-\alpha/2)}$ or $|Z_0| > Z_{1-\alpha/2}$.

Two-Sided p -Value: $2 \times (1 - \text{PROBT}(|T_0|, n-1))$ or $2 \times (1 - \text{PROBNORM}(|Z_0|))$.

Related SAS Procedure: PROC UNIVARIATE.

Description of and Notes on the Method:

- This test deals with paired data when the normality assumption cannot be fulfilled.
- Wilcoxon's sign-ranked test is the nonparametric version of the paired t -test.
- M_d = population mean of paired difference. n = number of non-zero pairs.
- The differences are ranked from lowest to largest with respect to the absolute value, and zeros are ignored.
- R^+ = sum of ranks related to positive differences, and R^- = sum of ranks related to negative differences.
- $\min\{R^+, R^-\}$ = smaller value of R^+ and R^- .
- m_i represents the number of ties for the i th value that has ties.
- The value of $\min\{R^+, R^-\} - n(n+1)/4$ is always non-positive.
- The "0.5" correction for continuity in the test statistic is not always needed. The absolute-value sign should be removed in the test statistic if "0.5" is not used.
- $$\text{sign}\left(\left|\min\{R^+, R^-\} - \frac{n(n+1)}{4}\right| - 0.5\right)$$
$$= \begin{cases} \left|\min\{R^+, R^-\} - \frac{n(n+1)}{4}\right| - 0.5 & \text{if } R^+ > R^- \\ -\left(\left|\min\{R^+, R^-\} - \frac{n(n+1)}{4}\right| - 0.5\right) & \text{if } R^+ < R^- \end{cases}$$
- A one-sided test can be performed in a similar manner to that for a t -test.

Group 2**One-Way Analysis of Variance**

Study Design: Parallel design.

Model Assumptions: Normal distribution, independence, equal variance for all treatments.

Number of Observations per Patient for PD Parameter: 1

Purpose: To compare the equal means of all treatment groups.

Statistical Model: $y_{ij} = \mu + \eta + \varepsilon_{ij}$ for $i = 1, 2, \dots, k$; $j = 1, 2, \dots, n_i$ where

- y_{ij} = PD value for patient j in treatment group i
- μ = unknown overall population mean
- τ_i = unknown treatment effect for treatment group i
- ε_{ij} = random error associated with patient j in treatment group i

Analysis of Variance Summary: See Table 3.

Computation for Sum of Squares:

$$SS(T) = \sum_{i=1}^k n_i (\bar{y}_i - \bar{y}_{..})^2, \quad SS(E) = \sum_{i=1}^k \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2$$

Table 3 Analysis of Variance Summary for Parallel Group Design

Source of variation	Degrees of freedom (d.f.)	Sum of squares (SS)	Mean squares (MS)
Treatment	$k - 1$	SS(T)	MS(T)
Error	$N - k$	SS(E)	MS(E)
Corrected total	$N - 1$	SS(TOT)	—

$$SS(TOT) = \sum_{i=1}^k \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_{..})^2,$$

$$MS(\text{Source } X) = \frac{SS(\text{Source } X)}{\text{d.f.}(\text{Source } X)}$$

$$\bar{y}_i = \sum_{j=1}^{n_i} \bar{y}_{ij} / n_i, \quad \bar{y}_{..} = \sum_{i=1}^k \sum_{j=1}^{n_i} y_{ij} / N, \quad N = \sum_{i=1}^k n_i$$

Hypothesis Testing for Treatment Effect:

- $H_0: \tau_i = 0$ for all i , vs. $H_a: \tau_i \neq 0$ for some i if treatment effect fixed.
- $H_0: \sigma_\tau^2 = 0$ vs. $H_a: \sigma_\tau^2 \neq 0$ if treatment effect is random.

Test Statistic for Treatment Effect: $F_0 = MS(T)/MS(E)$.

Rejection Region at α Level: $F_0 > F_{(k-1, N-k), 1-\alpha}$.

Two-Sided p Value: $1 - \text{PROBF}(F_0, k-1, N-k)$.

100(1 - α)% Confidence Interval for Treatment i :

$$\bar{y}_i \pm t_{(N-k, 1-\alpha/2)} \left(\sqrt{\frac{MS(E)}{n_i}} \right)$$

100(1 - α)% Confidence Interval for the Difference Between Treatments i and i' : $\bar{y}_i - \bar{y}_{i'} \pm t_{(N-k, 1-\alpha/2)}$

$$\left(\sqrt{MS(E) \left(\frac{1}{n_i} + \frac{1}{n_{i'}} \right)} \right)$$

Related SAS Procedure: PROC ANOVA or PROC GLM.

Description of and Notes on the Method:

- PROBF(x , df1, df2) is the cumulative probability function for an F distribution in SAS, and $F_{(df1, df2), \alpha}$ represents a numerical value at which the cumulative probability function is α under an F distribution with (df1, df2) degrees of freedom where $x = a$ random value.
- When the treatment effect is fixed, it implies that $\sum_i \tau_i = 0$. When it is random, it is normally distributed with a variance of σ_τ^2 .
- Typical examples in this group are a placebo-controlled clinical trial with two or more dosage levels of the investigational drug, and an active-controlled study with a study drug at one or more dosage levels and a comparator agent at one or more dosage levels.

Several important things that this approach always brings are:

- i. Departure of homogeneity of variance: First, use Bartlett's test to determine whether the variances are homogeneous.^[6] If not, log-transformed data or a generalized F -test, as discussed in Ref. [6], p. 360, may be used.
- ii. Multiple/pairwise comparison: In general, pairwise comparisons are needed when an overall F -test for treatment difference is significant and it is desirable to determine which pair(s) of the treatments contributes to the differences. Many procedures have been proposed, including Fisher's least significant difference (LSD) test, Bonferroni-Dunn test, Tukey's honestly significant difference (HSD) test, Newman-Keuls test, Scheffe test, and Waller-Duncan test. Another test, particularly useful for comparing several treatments with a control, is the Dunnett test (1955).^[7]
- iii. Dose response: It is well known that when a dose response is desirable in a clinical trial (i.e., an investigation on how the efficacy of the drug is related to the dosage given in the trial), a common design is to allow each patient to receive all or part of doses available in the study, in order to reduce variability. However, it is not uncommon to use a parallel group design for investigating the dose response. The trend of dose response can be evaluated by setting up orthogonal linear contrasts (linear, quadratic, cubic, quartic, etc.) of the treatment means (Ref. [8], pp. 117–138).
- d. The treatment effect can be fixed or random, depending on how the treatment levels are selected in the study. In either case, the test statistic remains the same, but the implication of the statistical conclusion will vary.
- e. When k (the number of treatment groups) = 2, the F -test is exactly the same as for a two-sample t -test.
- f. This F -test for analysis of variance is non-directional. More specifically, it would signal a "difference," but without showing the direction of either a "superiority" or an "inferiority." However, with the aid of multiple comparisons, a better picture of the direction may be observed.
- g. PROC ANOVA is mainly for the equal sample size case, and PROC GLM can handle unequal sample sizes.

Kruskal-Wallis Test

Study Design: Parallel group design.

Model Assumptions: Independence.

Number of Observations per Patient for PD Parameter: 1.

Purpose: To compare the equality of the median for all treatment groups.

Hypothesis Testing: $H_0: M_1 = M_2 = \dots = M_k$ vs. $H_a: M_i \neq M_j$ for some i, j .

$$\text{Statistical Method: } k_0 = \frac{\frac{12}{N(N+1)} \left(\sum_{i=1}^k \frac{R_i^2}{n_i} \right) - 3(N+1)}{1 - \frac{\sum_{j=1}^g m_j(m_j^2 - 1)}{N(N^2 - 1)}}$$

Rejection Region at α Level: $K_0 > \chi^2_{(k-1), 1-\alpha}$.

Two-Sided p Value: PROBCHI($K_0, k-1$).

Related SAS Procedure: PROC NPAR1WAY WILCOXON.

Description of and Notes on the Method:

- a. The Kruskal-Wallis test is a non-parametric version of analysis of variance to deal with PD parameters with more than two treatments. It is an extension of the Wilcoxon rank-sum test, just like analysis of variance is an extension of the two-sample t -test.
- b. The data are ranked from the lowest to highest over the combined data set.
- c. Let y_{ij} = the observation of the PD parameter for patient j in treatment group i , r_{ij} = the corresponding rank for y_{ij} , n_i = sample size for group i . Then $R_i = \sum_{j=1}^{n_i} r_{ij}$ and $N = \sum_{i=1}^k n_i$.
- d. Assume there are g categories in which m_j observations are tied in the j th category.
- e. PROBCHI(x) is a cumulative probability function at x for a chi-square distribution in SAS, and $\chi^2_{(k-1), 1-\alpha}$ is a numerical value at which the cumulative probability is $1 - \alpha$ for a chi-square distribution with $k - 1$ degrees of freedom.
- f. For k (the number of treatment groups) = 2, the Kruskal-Wallis test is identical to the Wilcoxon rank-sum test.
- g. Another approximation test procedure to employ is a one-way analysis of variance with the ranked data.
- h. Pairwise comparisons may be employed in two ways if the overall Kruskal-Wallis test is significant (Ref. [4], pp. 402–405):
 - i. Using the Wilcoxon rank-sum test for each pair of treatment groups, with a caution of adjustment for the α level.
 - ii. Using a method similar to the Bonferroni-Dunn test for analysis of variance by identifying the minimum required difference between the means of the ranks of any two groups

Log-Rank Test (Mantel-Cox Test)

Study Design: Parallel group design.

Model Assumptions: Independence.

Number of Observations per Patient for PD parameter: 1.

Purpose:

- To estimate the survival rate for each treatment group.
- To compare the survival curves over time for two or more treatment groups.

Kaplan-Meier Estimate for $S_i(t)$ for Treatment Group i :

$$\hat{S}_i(t) = \prod_{j=1}^t \left(\frac{n_{ij} - d_{ij}}{n_{ij}} \right)$$

100(1 - α)% Confidence Interval for $S_i(t)$:

$$\hat{S}_i(t) \pm Z_{1-\alpha/2} \sqrt{\frac{\hat{S}_i(t)(1 - \hat{S}_i(t))}{n_{i0} - c_{it}}}$$

Hypothesis Testing for Survival Curves:

$$H_0: S_1(t) = S_2(t) = \dots = S_k(t) \text{ for all time } t \quad \text{vs.} \\ H_a: S_i(t) \neq S_j(t) \text{ for some } i, j, \text{ and } t$$

Statistical Method: $Q_0 = \sum_{i=1}^k \frac{(d_{i+} - e_{i+})^2}{e_{i+}}$ where

$$d_{i+} = \sum_{j=1}^b d_{ij}, \quad e_{i+} = \sum_{j=1}^b e_{ij}, \quad e_{ij} = \frac{d_{+j} n_{ij}}{n_{+j}} \\ d_{+j} = \sum_{i=1}^k d_{ij}, \quad n_{+j} = \sum_{i=1}^k n_{ij}$$

Rejection Region at α Level: $Q_0 > \chi^2_{(k-1), 1-\alpha}$.

Two-Sided p Value: $1 - \text{PROBCHI}(Q_0, k - 1)$.

Related SAS Procedure: PROC LIFETEST.

Description of and Notes on the Method:

- This test applies to the PD parameter when the time to a specified event (e.g., death) is of most interest. This test allows a comparison of the Kaplan-Meier survival curve between two or more treatment groups. Patients who discontinue from the study before the first occurrence of the pre-defined event or patients who never experienced the pre-defined event during the entire course of the study are called *censored*.
- The study is divided into b time periods, denoted by t for $t = 1, 2, \dots, b$.
- $S_i(t)$ = survival rate at time t for treatment group i
 - d_{ij} = number of patients experiencing predefined event for treatment group i at time j
 - n_{ij} = number of patients for treatment group i at beginning of time j (i.e., number of patients at risk at time j)
 - n_{i0} = number of patients recruited to treatment group i
 - c_{it} = number of patients censored for treatment group i before time t

Table 4 displays information on the number surviving and not surviving for each treatment group for any given time j .

Table 4 Frequency Table for Survival and Non-survival

At time j	Survival		Row subtotal
	Yes	No	
Treatment 1	d_{1j}	$n_{1j} - d_{1j}$	n_{1j}
Treatment 2	d_{2j}	$n_{2j} - d_{2j}$	n_{2j}
$\vdots$	$\vdots$	$\vdots$	$\vdots$
Treatment k	d_{kj}	$n_{kj} - d_{kj}$	n_{kj}
Column subtotal	d_{+j}	$n_{+j} - d_{+j}$	n_{+j}

- There are several methods for obtaining the standard deviation for the Kaplan-Meier proportion. The one shown in the confidence interval was given by Parmar and Machin (1984).^[9]
- Another common test for survival curves is known as the log maximum-likelihood test.

Group 3

Fisher Exact Test

Study Design: Parallel group design.

Model Assumptions: Binomial distribution, independence.

Number of Observations Per Patient for PD parameter: 1.

Purpose: To compare the proportion of responders between two treatment groups.

Hypothesis Testing: $H_0: \pi_1 = \pi_2$ vs. $H_a: \pi_1 < \pi_2$

$$\text{Test Statistic: } p_0 = \sum_{x \leq x_1} \frac{\binom{n_1}{x} \binom{n_2}{r-x}}{\binom{N}{r}}$$

Rejection Region at α Level: $p_0 < \alpha$.

Observed Frequency Table: See Table 5.

Related SAS Procedure: PROC FREQ

Description of and Notes on the Method:

- The x in the test statistic refers to the count in the (1,1) position of the frequency table, and it is obtained by fixing n_1 , n_2 , N , and r in the observed frequency table.
- $\binom{x}{y} = \frac{x!}{y!(x-y)!}$
- The requirement of this method is that all of the values for the PD parameter be classified into two responses, regardless of the original measurement of the PD parameter.

Table 5 Observed Frequency Table

	Treatment 1	Treatment 2	Row total
Responder	x_1	x_2	$r (= x_1 + x_2)$
Non-responder	y_1	y_2	$y_1 + y_2 = N - r$
Column total	$n_1 (= x_1 + y_1)$	$n_2 (= x_2 + y_2)$	$N (= n_1 + n_2)$

- This test generally applies to studies with small sample size (< 20).
- π_i = the true unknown rate for responders for treatment group i .
- When $H_a: \pi_1 > \pi_2$ is desirable, we simply change the summation $x \leq x_1$ to $x \geq x_1$ in the test statistic.
- When $H_a: \pi_1 \neq \pi_2$ is desirable, the p -value is obtained by first computing the probabilities for all possible combinations having the same row and column totals as the observed frequency table. Then we add the probabilities for combinations that have a probability smaller than or equal to the observed one.
- This test can be generalized into a study with more than two responses and more than two treatment groups.

McNemar's Test

Study Design: Parallel group design.

Model Assumptions: Binomial distribution, dependence.

Number of Observations per Patient for PD Parameter: 2.

Purpose: To compare the proportions of responders between two treatment groups.

Hypothesis Testing: $H_0: \pi_1 = \pi_2$ vs. $H_a: \pi_1 \neq \pi_2$

$$\text{Test Statistic: } Q_0 = \frac{(|B - C| - 1)^2}{B + C}$$

Rejection Region: $Q_0 > \chi^2_{1, 1-\alpha}$.

Two-Sided p Value: $1 - \text{PROBCHI}(Q_0, 1)$.

100(1 - α)% Confidence Interval for $\pi_1 - \pi_2$:

$$\frac{B - C}{n} \pm z_{(1-\alpha/2)} \frac{1}{n} \sqrt{B + C - \frac{(B - C)^2}{n}}$$

Observed Frequency Table: See Table 6.

Related SAS Procedure: PROC FREQ.

Description of and Notes on the Method:

- Each patient contributes two observations under two conditions, such as before and after treatment, or under two different treatments, or at two different time points.
- This assumes patients' well-being with regard to the PD parameter are the same before treatments. This assumption, in reality, may not be true.
- π_1 is estimated by $(A + B)/N$, and π_2 is estimated by $(A + C)/N$.
- The quantity "1" in the test statistic is a correction for continuity, which may not be needed for the analysis.

- The chi-square test statistic without the correction for continuity is also equivalent to a Z -test statistic of the form $Z_0 = (B - C)/\sqrt{B + C}$, which follows a standard normal distribution and is useful for a one-sided test.
- The McNemar test has been extended to a $k \times k$ ($k > 2$) case in the Stuart-Maxwell test^[10] (i.e., for studies with k treatment groups and k responses).

Group 4

(Pearson's) Chi-Square Test

Study Design: Parallel group design.

Model Assumption: Multinomial distribution, independence.

Number of Observations per Patient for PD Parameter: 1.

Purpose: To determine and compare the relationship between the PD parameter and the explanatory variable.

Hypothesis Testing: $H_0: \pi_{ij} = (\pi_i)(\pi_j)$ for all i, j vs. $H_a: \pi_{ij} \neq (\pi_i)(\pi_j)$ for some i, j

$$\text{Test Statistic: } Q_0 = \sum_{j=1}^k \sum_{i=1}^m \frac{\left(\left| n_{ij} - \frac{n_{+j}n_{i+}}{n_{++}} \right| - 0.5 \right)^2}{\frac{n_{+j}n_{i+}}{n_{++}}}$$

Rejection Region at α Level: $Q_0 > \chi^2_{(m-1)(k-1), 1-\alpha}$.

Two-Sided p Value: $1 - \text{PROBCHI}(Q_0, (m-1)(k-1))$.

Observed Frequency Table ($m \times k$ Table): See Table 7.

Related SAS Procedure: PROC FREQ.

Description of and Notes on the Method:

- π_{ij} = unknown true proportion for having response i in treatment group j
 - π_i = unknown true proportion for having response i regardless of treatment group
 - π_j = unknown true proportion for treatment group j regardless of responses
- The null hypothesis indicates the independence between treatment group and response.
- There is another type of hypothesis testing for a chi-square test concerning a test for homogeneity; it means all proportions for all cells are the same.
- The quantity "0.5" in the test statistic is the "continuity correction." An absolute value for the difference in the denominator is always needed when the "continuity correction" is considered. The "continuity correction" in the test statistic may not be needed.

Table 6 Observed Frequency Table

Trt 1	Trt 2		Row total
	Responder	Non-responder	
Responder	A	B	A + B
Non-responder	C	D	C + D
Column total	A + C	B + D	N (= A + B + C + D)

Table 7 Observed Frequency Table ($m \times k$ Table)

	Treatment 1	Treatment 2	...	Treatment k	Row total
Response 1	n_{11}	n_{12}	...	n_{1k}	n_{1+}
Response 2	n_{21}	n_{22}	...	n_{2k}	n_{2+}
$\vdots$	$\vdots$	$\vdots$	...	$\vdots$	$\vdots$
Response m	n_{m1}	n_{m2}	...	n_{mk}	n_{m+}
Column total	n_{+1}	n_{+2}	...	n_{+k}	n_{++}

- e. There are a number of arguments about using the chi-square test (Ref. [4], p. 218):
- i. Do not use the chi-square test when $n_{++} < 20$.
 - ii. All n_{ij} s are at least 5 if $20 \leq n_{++} < 40$.
 - iii. All expected cell frequencies are at least 1 if $n_{++} \geq 40$.
 - iv. For a 2×2 table with $n_{++} < 20$, Fisher exact test is suggested.
- f. Another approach to handling an $m \times k$ table is to employ a likelihood-ratio chi-square test with the test statistic expressed as follows:

$$G^2 = 2 \sum_j \sum_i n_{ij} \log \left(\frac{\frac{n_{ij}}{n_i + n_{+j}}}{\frac{n_{++}}{n_{++}}} \right)$$

This test statistic also follows a chi-square distribution with $(m - 1)(k - 1)$ degrees of freedom.

CONCLUSION

Because there are potentially many other different cases that may arise in a clinical setting, this entry only a purpose of covering mostly known cases and the most commonly used statistical methodologies.

Abstract

The purpose of this entry is to provide an overview of the terminology, family of technologies, and key methodologic features of health economic evaluations. The primary focus is on the statistical considerations of planning and analyzing studies and interpreting the results.

INTRODUCTION

The evaluation of pharmaceutical and biological products has traditionally focused on considerations of safety and efficacy. Federal regulation requires that studies of safety and efficacy be conducted before a product is approved and marketed, and as a result, the methods for product development have been enhanced. In recent years, the information needs of health care decision makers has expanded beyond the traditional measures of safety and efficacy to include patient outcomes, cost, and cost-effectiveness. The primary motivation for this shift is a growing concern over the cost of health care; the current availability of health-related interventions exceeds society's ability and willingness to pay. One important consequence in the changing focus of health care decision making is the need for appropriate methods and decision rules to guide choices toward interventions most likely to yield the greatest value for the level of investment. "Health economics" is a field of study that applies economic concepts to health and health-care systems. An important topic in health economics is the evaluation of health care treatments and programs on the basis of costs (inputs) and consequences (outputs). "Pharmacoeconomics" focuses on economic evaluations of the use of pharmaceutical products, programs, and services. The purpose of this article is to provide an overview of the terminology, family of technologies, and key methodologic features of health economic evaluations. The primary focus is on the statistical considerations of planning and analyzing studies and interpreting the results.

IMPORTANCE OF ECONOMIC EVALUATION

The concern over the rising costs of health care has prompted several initiatives that influence the price, availability, or use of medicines. Many hospital and managed

care pharmacies have a strict budgeting process for providing pharmaceutical products and services. Suboptimal decisions are sometimes made in this setting when the pharmacy decisions are not coordinated with the larger health care system. For example, it is possible that the use of a new, higher-priced antibiotic would cause an increase in the pharmacy budget yet may reduce costs overall if the use of the antibiotic were associated with shorter lengths of hospital stay or a reduced rate of reinfection. For this reason, many hospitals and managed care organizations have lists, called "formularies," of selected pharmaceuticals and the dosages judged to be the most appropriate or cost advantageous for patient care. Physicians who practice as part of a managed care provider organization are required or encouraged to prescribe from the formulary. Many managed care organizations also recommend specific disease-management programs of care as a guideline for practicing physicians. Many countries maintain drug formularies at the national level to determine the reimbursement level for drugs. Other initiatives are specifically directed at prices; one example used in Germany and the Netherlands is a practice called "reference-based pricing," in which product reimbursement is set at the same level for all drugs in a therapeutic class. The reference price is usually set according to the least expensive drug in the class. Reference-based pricing is becoming more common worldwide as a way to control health care costs.

Another sign of the increasing importance of economic evaluations in health care decision making has been the emergence of guidelines for the conduct of cost-effectiveness analyses. The purpose of the guidelines has been to encourage a rational diffusion and application of medical technologies. Australia^[1] and Ontario, Canada,^[2] have proposed guidelines for the provision of cost-effectiveness data before drugs are listed on the national or provincial formulary. Several European countries have also implemented guidelines.^[3] The U.S. Food and Drug Administration^[4]

applies strict standards to claims of cost-effectiveness by pharmaceutical companies. These standards include the use of adequate and well-controlled studies demonstrating evidence for the comparative claims about the drugs in question. Marketing statements about drugs and vaccines that are not drawn directly from the product label generally require the same level of evidence as claims. Major medical journals, including *The New England Journal of Medicine*^[5] and the *British Medical Journal*^[6] have issued guidelines for the design and reporting of economic evaluations considered for publication. Most recently, the Panel on Cost Effectiveness in Health and Medicine, sponsored by the U.S. Public Health Service, reported recommendations on standardized methods for conducting cost-effectiveness analyses.^[7,8] Whereas most guidelines have dealt specifically with the methodologic aspects of studies, Hillman et al.^[9] discussed guidelines for the conduct of studies sponsored by pharmaceutical companies.

These initiatives have also resulted in an increased level of competition among pharmaceutical companies to make comparative claims on the basis of pharmacoeconomic outcome variables, including resource use, cost, and cost-effectiveness. Many clinical development programs now include pharmacoeconomic objectives, which can greatly affect the overall design and implementation of clinical trials. Nonclinical studies of disease epidemiology and the costs of treating the targeted diseases are also common in clinical development programs as a way of supplementing trial data. These changes have broadened the traditional roles and responsibilities of the clinical trial statistician.

Finally, the Academy for Managed Care Pharmacy (AMCP) has proposed a standard format for the provision of cost-effectiveness data to managed care plans. Although this does not constitute a formal requirement, it might lead to more plans requesting such data.^[10]

TYPES OF ANALYSES

Economic evaluations of health care technologies involve a formal assessment of the costs and consequences of medical treatments or treatment programs. The major components of an economic evaluation include identifying, measuring, and valuing both the resources applied to the health care program (inputs) and the health improvements derived from the health care program (outputs). The theoretical foundation of the assessment is the concept of economic efficiency, in the sense of optimizing health outcomes for given fixed levels of resources consumed.^[11, 12] The basic model recognizes that all health care interventions involve costs (measured in terms of the economic value of the resources used to treat or prevent illness) and health consequences (such as improvements in health status) and may include savings in future health care costs.

One type of study often conducted at the start of a health economic research program is a "burden-of-illness study."

This form of analysis typically combines epidemiologic data on the incidence and prevalence of the disease with cost data in order to estimate the total direct and indirect cost attributable to a disease incurred by the population over a defined period. Burden-of-illness studies are useful for influencing prioritization by alerting policy makers and health care professionals to the importance of a problem. Several important issues have been raised about the conduct and use of these studies. Drummond^[13] noted that their use is limited because they are essentially non-comparative and therefore do not indicate whether more or less resource should be devoted to treatment. In addition, the methods for estimating the value of lost productivity and reduced productivity are thought to possibly exaggerate those costs. This might arise at the societal level, e.g., because lost labor can usually be replaced if the workforce is not at full employment. At the other extreme, burden of illness studies do not account for the intangible costs related to a diminished quality of life, or for the impact of the disease on others in the form of grief. They can, however, provide a benchmark against which a new intervention can be evaluated.

Comparative economic evaluations provide the most useful information for guiding health care decisions. Researchers have developed several forms of comparative economic analysis, which can broadly be classified into the following groups:^[14] cost analysis, cost-consequences analysis, cost-effectiveness analysis, cost-utility analysis, and cost-benefit analysis.

A complete evaluation of therapy costs is needed for all forms of economic analyses. In a "cost analysis," or "cost-minimization analysis," the comparison is based on an accounting of the resources used as input to the therapy or health care program. This form of analysis is used when the effectiveness of the candidate and comparative therapies can be assumed to be equal and when the comparison is made strictly on an evaluation of costs. Although therapies are rarely equal in terms of effectiveness, cost minimization can provide a reasonable approximation in some cases. For example, de Lissoy et al.^[15] performed a cost analysis of imipenem and cilastatin compared with tobramycin plus clindamycin for the treatment of patients suspected of having acute intra-abdominal infection. The study compared hospital treatment costs during an episode of infection for patients enrolled in a clinical trial comparing the effectiveness of the two therapy groups. Costs of hospital stays in regular and intensive care units, medical procedures, antibiotics, other drugs, and laboratory evaluation were included in the analysis. The mean total costs did not differ significantly between the two treatment groups (\$12,040 for imipenem and cilastatin and \$11,220 for tobramycin plus clindamycin); however, the study showed that costs were significantly affected primarily by the severity of illness, as measured by Acute Physiology and Chronic Health Evaluation acute physiology score. Use of a cost-minimization analysis for this study was

conservative for imipenem and cilastatin because the principal finding in the main clinical study was a lower incidence of treatment failure in patients in the imipenem and cilastatin group ($P = 0.043$). This is not only an important health outcome but is an additional source of costs that was not included in the economic evaluation.

A “cost-consequences analysis” extends the cost-minimization analysis by also considering health outcomes. This study displays complete but separate enumerations of the costs and health outcomes (measured in natural units) of the candidate therapies. Because the results are presented in a disaggregated form, the overall analysis of the study is left to the user; no specific value is placed on the outcomes. Cost-consequences analyses are most useful to analysts who have the technical ability to use the reported results as a basis for applying their own methods of evaluation.

A “cost-effectiveness analysis” measures the health outcomes of the candidate treatment programs in natural units. Examples include variables such as life-years gained, fractures avoided, and coronary events avoided. In the classic form of cost-effectiveness analysis, the results are expressed by the ratio cost per unit of health benefit gained as a measure of efficiency. For example, Oster and Epstein^[16] used an epidemiologic model based on the Framingham Heart Study to evaluate the cost-effectiveness of pharmacologic therapy for reducing cholesterol levels. They estimated that for a 40- to 44-year-old man with elevated serum cholesterol levels, therapy with the pharmaceutical agent cholestyramine costs \$76,500 per additional life-year gained.

A “cost-utility analysis” is a form of cost-effectiveness analysis that values the consequences of treatment programs by using health state preference scores or utility weights. For example, this method allows assessments on the quality of life-years gained, not just the crude number of years. This approach is particularly useful for evaluating treatments that may extend life expectancy (possibly by preventing fatal disease in the future) but may be associated with adverse experiences in the short term. Cost-utility analyses also provide a common metric for overall reductions in morbidity and mortality. For the broader policy perspective, this allows comparisons across treatments for different diseases or even for comparisons of treatment versus prevention strategies. In the U.S. literature, cost-utility analyses are rarely used.

A “cost-benefit analysis” evaluates health outcomes in monetary terms rather than in terms of patient outcome. This approach makes the measure of health benefit commensurate with resource costs. This may be the broadest form of analysis because it allows direct assessment of the benefits of the treatment program with respect to the costs and has the potential to capture significant nonhealth benefits. Two methods for capturing monetary value to health states are used most often.^[14,17] The “human capital method” evaluates health benefits in terms of the

economic productivity gained from the increased survival or decreased morbidity. Wage rates are typically used for the analysis. The “willingness-to-pay” method defines the maximum amount of money an individual is prepared to spend to secure a defined health state. Both methods present significant analytic challenges,^[7,14] but the willingness to pay approach is considered by most economists to be the more theoretically correct because it recognizes the impact of mortality and morbidity on aspects of life beyond employment, such as housework and leisure time.

There are still relatively few willingness-to-pay studies in the health economics literature. In one example, O'Brien et al.^[18] asked enrollees in a health maintenance organization whether they would be willing to pay to upgrade their insurance coverage to include a new supportive drug used in cancer chemotherapy.

DESIGN CONSIDERATIONS

Study Perspective

The perspective of the economic evaluation determines which costs and health outcomes are relevant and plays an important role in how they should be valued. Possible study perspectives include that of the patient, employer, health care provider, hospital, managed care organization, insurance company, or society at large. Gold et al.^[7] recommended using the “societal perspective” because it is the most comprehensive and is relevant to the broad allocation of resources. This perspective includes a complete evaluation of the health effects and costs experienced by anyone significantly affected by the intervention. Economic evaluations of pharmaceutical products often use a narrower perspective that would be relevant to specific customer segments. The study perspective is an important design feature and should be defined early in the study process. Drummond et al.^[14] recommended performing the evaluation for various sectors and combining results to allow the study to potentially address questions from several perspectives. This approach might be useful if for example the evaluation is intended to address costs that may be incurred by a managed care organization or a hospital and the benefits applied to specific patient populations.

Costing Methods

Three general categories of costs may be examined within an economic evaluation of a health care technology: direct costs, indirect costs, and intangible costs.

“Direct costs” include the value of medical resources used in the provision of the treatment and the consequences of the treatment, both in terms of beneficial effects or unwanted side effects. For pharmaceutical programs, direct costs include the costs of drugs, medical staff, medical facilities, medical procedures, diagnostic and

laboratory tests, and supplies. When appropriate, direct nonmedical costs, which are borne by the patient seeking care, may be included in the analysis. These would include the costs of transportation, child-care, housekeeping, and so forth. Several authors have discussed methods for assigning direct costs to units of health care resources;^[14,19] such discussion is beyond the scope of this paper. Most studies capture patient-specific data on the health care resources used for treatment and then conduct separate studies to estimate costs for these resources. Patient-level cost data can then be computed by combining the cost and resource data from the trial.

“Indirect costs” include the value of productivity lost because of the underlying illness or its treatment. Luce et al.^[19] referred to these costs as “productivity costs” to avoid confusion with the term as it is used by accountants for overhead costs. They include the costs associated with lost or impaired ability to work or to engage in leisure activity because of illness and lost economic productivity caused by premature death. Historically, the “human capital approach” has been used to estimate productivity costs, but this method has been criticized for its use of gross earnings that include employee benefits. It is argued that using earnings raises both ethical and equity concerns because this method does not place a value on unpaid employment (e.g., homemaking) and may undervalue the impact of the disease on women and the elderly. In addition, the method may overestimate the true costs because short-term losses in productivity may be lower than average wage rates. For longer-term losses, companies can replace laborers to minimize losses in production. In this context, Koopmanschap and Rutten^[20] proposed a “friction cost” approach based on the notion that the amount of production lost depends on the time span that organizations need to restore the initial production level. Their estimates for the Netherlands in 1988 show that the human capital method can provide estimates that exceed the friction cost by a factor of 10. Luce et al.^[19] recommended that productivity costs be estimated and reported separately in cost-effectiveness analysis to avoid double counting the beneficial effects of treatment.

Outcomes such as reduction of pain, emotional well-being, social functioning, activities of daily living, mobility, and cognitive functioning are all important considerations in the economic evaluation of a pharmaceutical treatment program. Failure to include these factors reduces the credibility of the assessment and may threaten its adoption by decision makers. The value associated with these types of outcomes has been called “intangible benefits.”^[14] These measures are often captured in clinical trials by using validated quality-of-life instruments. For purposes of economic evaluation, their impact is included as part of the effectiveness measure in a cost-utility analysis. Monetary values of intangible outcomes would be (implicitly) included in the willingness-to-pay method.

Outcome Measures

Because economic evaluation focuses on efficiency, measuring the benefit of the intervention in terms of health outcomes is as important as measuring benefit in terms of cost. Several approaches have been used, and there is no clear consensus on the end points to use for the evaluations.^[17] The choice is often driven by complexities in the measurement instruments and by possible limitations in the design of the clinical programs. Short-term “surrogate, or intermediate, measures” of response to treatment are attractive in these situations when they provide reliable indicators of long-term patient outcome. For example, in the area of cardiovascular disease, meta-analysis^[21] and long-term clinical trials^[22,23] have shown that lowering serum cholesterol levels confers the benefits of a reduced risk for coronary heart disease and increased survival and thus supports the cholesterol hypothesis. These findings established the rationale for a cost-effectiveness analysis based on intermediate endpoints by Schulman et al.^[24] These researchers reported a comparative analysis of various lipid-lowering drugs by plotting percentage reduction in cholesterol levels by the 5-year cost of patient management associated with the use of each drug. Economic evaluations based on intermediate endpoints assume that the effect of therapy on the ultimate clinical endpoint is fully captured through an established relationship with the surrogate marker. This assumption can be difficult to validate without the appropriate long-term clinical trials.

Cost-effectiveness analyses can also be based on different types of “clinical end points,” such as coronary events avoided or fractures avoided. An advantage of using end points prevented as the effectiveness measure is that they are closely related to the clinical objectives of therapy. This makes ratios such as cost per event avoided a meaningful measure for decision makers. When the medical condition is potentially life-threatening, “mortality end points” such as deaths avoided are applicable. One common measure of cost-effectiveness that has been used for medical evaluations is the “cost per life-year gained.” The advantage of using life-years gained is that this measure has a very clear definition as the difference between the treatment groups in the areas under the respective survival curves. As such, it takes into account the number of life-years during which the risk for death is reduced. The obvious disadvantage of mortality end points is that they do not apply to the evaluation of treatments for non-life-threatening illnesses and do not consider the patient’s quality of life.

The quality-adjusted life-year (QALY) method^[25] is an attempt to combine the concepts of quality and length of survival. The QALY method uses measures of health outcome that assign, for each period of time, an overall measure of a patient’s quality of life by using a weight defined from 0 (death) to 1 (perfect health). Health states with diminished quality are scored less than 1. The number of

QALYs is simply the sum of the QALY weights over the time horizon for the evaluation. The number of QALYs gained is a popular measure of effectiveness used in cost-utility analyses.

The QALY concept is not without controversy. This measure can be interpreted as the number of years of perfect health a patient values equivalently to their years with diminished quality. For example, a QALY of 1 could be derived from a single year with perfect life or from several years with diminished quality. Mehrez and Gafni^[26] argued that patients would value the same number of QALYs differently depending on the path by which the QALYs are accumulated. They proposed a healthy years equivalent (HYE) measure that is derived by using a complex two-step procedure to determine patient preferences for different paths for accumulating QALYs. At the other extreme, Cox et al.^[27] argued that the QALY approach is overly complex and that simpler measures addressing the dimensions of quality of life (such as physical or mental well being) and survival separately should be used.

The end point chosen is an important factor in economic evaluations. Drummond et al.^[28] showed that the choice of end point can have an important impact on the ranking of alternative therapies for lipid lowering. The ranking depended on the value placed on life-years after coronary heart disease developed, the effect that drug therapy had on quality of life, and even the discount rate at which future QALYs were valued. Ultimately, the selection of end points depends on the nature of the disease and treatment program being studied, and, if this can be determined, what is most relevant to the decision makers.

Discounting

Economic evaluations should include the value of all costs, adverse experiences, and benefits that are the direct consequence of the disease or treatment program under study. This may include a stream of costs and health effects over a long period of time. It is important to recognize that the costs and benefits may vary over time and may be different for the programs under study. For example, the cost of drug therapy to reduce serum cholesterol levels is incurred with the initiation of therapy, but the benefits are realized through a reduced risk for coronary heart disease in later years. In addition, comparisons of drug therapy with surgical procedures need to account for the different timing of costs and benefits.

The method of “discounting to present values” is used to account for the timing of the stream of costs and health benefits. Computationally, $PV(X) = \sum X_i / (1 + r)^i$ gives the present value for the stream of costs or health effects, denoted by X_i for year i , using a discount rate r . The value assigned to r is an important and controversial design consideration, as is the notion of discounting both future costs and future health effects at the same rate. For example,

Van Hout^[29] argued that different discount rates may be required for costs and effects. The Panel on Cost Effectiveness in Health and Medicine^[7,8] recommended discounting costs and health outcomes at the same 3% discount rate. A riskless 3% discount rate was chosen to be consistent with the real rate of return on long-term U.S. government bonds. To maintain comparability with previously published analyses, they recommend also using a 5% rate and conducting a sensitivity analysis for rates ranging from 0% to 7%. Undiscounted gains in life expectancy and quality-adjusted life expectancy can be reported separately as they are often of interest to the reader.

RESEARCH METHODS

A variety of research methods have been used for economic evaluations, including modeling designs and studies using clinical economic trials that involve prospective or retrospective data collection.

Modeling Studies

Modeling studies have employed two main types of methods to simulate patient outcomes and cost by using assumptions about the effects of therapy. Clinical “decision-analytic models” systematically lay out all probable pathways and consequences of the candidate treatment programs in a decision tree. The likelihood and expected cost of each pathway are estimated by use of data from clinical trials or epidemiologic investigations. These models have been used mostly for treatments for acute conditions, which may resolve in a short period. “Markov models” are used for diseases and treatments that are characterized by recurrent disease states or treatment programs.

“Epidemiologic models” have been used for disease areas in which the outcomes are related to sets of risk factors and the clinical outcomes may take years to develop. Several models for the treatment of elevated cholesterol levels have been developed on the basis of data from the Framingham Heart Study.^[16,30,31] These models estimate the risk for coronary heart disease according to pretreatment and posttreatment cholesterol levels by using risk equations derived from the Framingham study and by using estimates of treatment efficacy derived from short-term clinical trials. Similar types of models have been developed for osteoporosis and HIV infection on the basis of epidemiologic links between clinical outcomes and risk factors that can be altered by treatment.

Clinical-Economic Trials

The collection and analysis of economic data in clinical trial settings is becoming more common. These types of studies have been called “piggyback studies,” a term denoting that the scope of the trial was broadened to address economic

questions in addition to the clinical evaluation. Typically, they are undertaken during Phase III of the drug development process. Many of these studies have the advantages of being multicenter, randomized, double-blinded, and placebo-controlled—features that offer a high degree of internal validity to allow researchers to address specific questions about the safety and efficacy of the candidate treatment.

Studies of this type, however, have important drawbacks for economic evaluations.^[32,33] They may have insufficient sample size for addressing questions about cost and, more important, lack generalizability and external validity because of the use of a comparator (often placebo) that may be inappropriate in a real-world setting. Moreover, the studies are usually conducted in specialized medical centers with restrictive patient populations, and they define patient care by using rigorous clinical protocols in which the physician is blinded to knowledge of treatment. All of these factors limit the usefulness of these studies in providing data to answer questions about the cost and consequence of therapies as they will be used in real-world settings.

Schulman et al.^[34] and Mauskopf et al.^[35] discussed strategies for undertaking economic assessment within the Phase I through Phase IV clinical development program. Drummond and O'Brien^[36] and O'Brien and Drummond^[37] addressed issues of clinical and statistical significance in the context of socioeconomic evaluations of medicines. They recommended using confidence interval methods instead of strict accept/reject hypotheses as a way to permit the readers of the published findings to assess the magnitude and significance of the observed differences. Schulman et al.^[38] discussed their attempts to overcome these limitations in the economic evaluation of the Flolan® International Randomized Survival Trial (FIRST), a multinational Phase III clinical trial of Flolan® in the treatment of congestive heart failure. Freeman-tle and Drummond^[39] addressed the issue of blinding in clinical-economic trials, noting that blinding may lead to artificialities in treatment protocols that may affect costs and potential benefits.

An alternative to the piggyback design is the “randomized clinical economic trial” done expressly for cost-effectiveness analysis. Oster et al.^[40] discussed the design of a randomized trial intended to assess effectiveness and cost of two cholesterol treatment programs that involved stepped-care regimens with several drug choices. One treatment program was modeled after the 1988 guidelines of the National Cholesterol Education Program. This stepped-care approach recommended initiating niacin therapy and then introducing a series of other pharmacologic agents until the low-density lipoprotein cholesterol levels attained target levels. The other program was a regimen that started with the HMG-CoA reductase inhibitor lovastatin and allowed changes in therapy if the target level was not attained or if the patient preferred to switch therapy. Lovastatin was also allowed in the final step of

the stepped-care regimen. The study was conducted in a managed care setting; after randomization, patient management approximated usual clinical practice. Provider compliance with the treatment plans was encouraged but not enforced, and patients paid for medication as they customarily would. Another feature of the study is that it used the intention-to-treat principle for both design and analysis because patients in the different program groups may actually have been prescribed the same drug at some points in the trial.

“Prediction models” can also be developed using the clinical and health care utilization data collected during the main trial. This allows the analysis to consider, e.g., questions about longer time horizons or specific patient subgroups. Mark et al.^[41] supplemented data from the 1-year Global Utilization of Streptokinase and TPA for Occluded Arteries (GUSTO) study with data on projected life expectancy and hospital cost data to evaluate the cost-effectiveness of tissue plasminogen activator compared with streptokinase for acute myocardial infarction. By using cost-effectiveness analysis, the authors concluded that the added costs of tissue plasminogen activator therapy were consistent with those of other well-accepted medical technologies when evaluated in comparison to the benefits of therapy. Similarly, the Diabetes Control and Complications Trial (DCCT) group^[42] examined the cost-effectiveness of aggressive approaches to the management of insulin-dependent diabetes mellitus. They used a Monte Carlo simulation model that was based on the clinical end point results of the DCCT and was supplemented with other clinical, epidemiologic, and cost studies. Both of these studies used novel modeling techniques and secondary sources of data to overcome limitations in the designs of the main studies to answer the relevant economic questions.

METHODS OF ANALYSIS

Much attention has recently focused on statistical methods for assessing uncertainty in health economic evaluations.^[43–45] Uncertainty in the estimate of program costs and effects arises from two primary sources. The first is uncertainty in assumptions about the form of the underlying economic model, including values for the key model parameters, such as the time horizon or discount rate. In other situations, economic models use point estimates for parameters relating to patient outcomes or cost. O'Brien et al.^[46] calls this first type of evaluation a “deterministic analysis” and recommend that uncertainty be assessed by using a comprehensive “sensitivity analysis.” Briggs et al.^[47] discuss the different forms of sensitivity analysis that can be applied. These may include simple reporting of the results over a range of parameters, an analysis of extremes, or a threshold analysis. Probabilistic sensitivity analyses are also used in some studies.

The second source of uncertainty is sampling variability in model variable estimates, which are derived from studies of individual patients. This type of evaluation is called a “wholly stochastic analysis,” and formal statistical analyses can be used to estimate variability and to construct the 95% confidence interval estimates of the key economic parameters. Evaluations that involve uncertainty from both model parameters and sampling variability are called “partially stochastic analyses.” The rest of this section briefly discusses the statistical considerations involved with analyzing cost data and conducting cost-effectiveness evaluations.

Analysis of Cost Data

Analysis of cost data should first determine whether treatment programs differ in the actual resources utilized (e.g., hospitalization, procedures, and drug use). A candidate treatment may reduce one type of resource but increase another type. Computing patient cost involves combining resource data with prices in a way that is consistent with the study perspective. The statistical analysis of cost data can present several potential challenges. The distribution of costs is typically right-skewed, with a few patients incurring very large costs. Use of summary measures that are insensitive to extreme values, such as the median, are usually not desirable to organizations attempting to manage total aggregate patient costs. Patients with high resource use are substantial contributors to aggregate treatment costs but have a small influence on the median.

Cost distributions also tend to exhibit large variability that can pose problems for the provision of accurate and precise estimates of cost differences with the appropriate level of statistical power. The variability in cost data often increases with mean cost to such a degree that the usual normalizing and variance-stabilizing transformations are not helpful. For these reasons, nonparametric methods, resampling methods (e.g., bootstrap methods), and randomization tests may be preferred to parametric tests done by using analysis of variance. Heyse et al.^[48] provided an overview of statistical considerations in analyzing cost and utilization data.

Another important complication relates to patient cost data that are subject to right censoring. Censoring occurs whenever study data on patient outcomes collected over time are incomplete. Difficulties arise in the analysis because only partial data on some patients are available. This situation can arise because of study design considerations (e.g., a clinical trial uses a rolling enrollment period and a fixed study termination) or because a patient is lost to follow-up. The latter can occur for many reasons: for example, patients may transfer to other health care providers or drop out of the study because of the treatment's poor efficacy or adverse effects. Patient censoring due to death provides several challenges in the statistical analysis. Some

authors consider patient death a censored observation for cost analysis. For example, Dudley et al.^[49] suggested that for cost studies of surgical procedures, deaths should be treated as censored observations so that hospitals with high mortality rates and therefore lower costs are not rewarded. The alternative argument is that patient death presents a well-defined end point for the accumulation of costs and therefore is uncensored.

Recently, health economists have shown interest in statistical methods to estimate mean costs when data for some patients are right censored. Dudley et al.^[49] compared several analytic models, including both parametric and nonparametric survival models for estimating the effects of clinical factors on the hospital costs of coronary bypass graft surgery. Fenn et al.^[50] pointed out the biases that result when the censored observations are either excluded from the calculations (called the uncensored method) or included as complete observations (the full sample method). They suggested using the Kaplan–Meier estimators to incorporate the censoring information. However, Carides and Heyse^[51] showed that direct application of this method can also result in a substantial bias.

Lin et al.^[52] proposed a method that uses the sample mean costs for patients who die within distinct time intervals defined for the study (e.g., monthly or yearly intervals). These interval means are combined with Kaplan–Meier estimates of dying within the interval to obtain an estimate of mean cost. Carides et al.^[53] improved on the method of Lin et al. by using a two-stage estimator that first fits the uncensored patient cost data to an appropriate statistical model using linear or nonlinear regression and then applies Kaplan–Meier survival estimation to the fitted values. Both methods are statistically consistent and have only a slight bias in small samples but the two-stage method gains efficiency from the modeling or smoothing that occurs during the regression stage. A final method proposed by Zhao and Tsiatis^[54] for estimating the distribution of quality-adjusted survival times was modified by Bang and Tsiatis^[55] to estimate the survival distribution for costs. This method computes the weighted sum of the number of patients with costs exceeding a specific value y . The weights are directly related to the censoring probabilities at each time point. The distribution can then be used to compute summary statistics such as the mean. A disadvantage is that the estimator can be highly unstable for small weights.

Cost-Effectiveness Ratios

The cost-effectiveness of a candidate treatment or treatment program is typically evaluated by using the “incremental cost-effectiveness ratio,” defined by the equation

$$R = \frac{\Delta C}{\Delta E} = \frac{C_B - C_A}{E_B - E_A}$$

where C_A and C_B are the mean costs associated with treatments A and B and E_A and E_B are the mean health effects associated with these treatments. The incremental cost-effectiveness ratio R measures the additional cost per additional unit of health outcome for therapy B relative to therapy A.

Point estimates of R , denoted by $\hat{R} = \Delta\hat{C}/\Delta\hat{E}$ have typically been reported for clinical trials by using average between-treatment costs and effects. Recent reports in the literature have emphasized the need to provide 95% confidence interval estimates of R to account for the inherent variability of the estimates. Computing interval estimates of R is also important because the limited sample sizes used in clinical trials are usually not sufficient to detect differences in mean cost between therapies, or to get precise estimates of cost-effectiveness ratios.

Several methods have been proposed for estimating cost-effectiveness ratios using 95% confidence intervals. These include the use of a Taylor series approximation for the variance of $\hat{R}$ ^[46] and application of Fieller's theorem^[56–58] for estimating 95% confidence limits for the ratio of two random variables. A box method was proposed by Wakker and Klaassen^[59] and extended by Laska et al.^[58] This method provides a conservative upper-bound estimate of R by using the separate 95% confidence interval estimates of ΔC and ΔE . In addition, a bootstrap estimate of R was suggested by O'Brien et al.^[46] and further developed by Chaudhary and Stearns.^[56] The latter authors provide a nice overview of the Taylor series, Fieller's theorem, and the bootstrap method. They also give specific formulations to apply to each of those methods. Polsky et al.^[60] used simulation methods to compare the box method, Taylor series, Fieller's theorem, and bootstrap for this application. They conclude that the bootstrap and Fieller's theorem were more dependably accurate than the others because they allow for the asymmetric shape of the sampling of distribution of $\hat{R}$. Moreover, the box method does not account for the correlation between costs and effects.

Most of the difficulties encountered with the available methods for confidence interval estimates of cost-effectiveness ratios are related to situations in which ΔE is numerically small. The problem is heightened when the estimate of R is based on estimates of ΔE from clinical trials. Even if the null hypothesis that $\Delta E = 0$ is rejected, the treatment effects on the health outcome variable may be numerically small or modest. All of the available methods deal with the problem of small denominators in different ways. The accuracy of the Taylor series approximation depends on having small coefficients of variation for the separate estimates of between treatment differences in both costs and effects. The accuracy of the approximation begins to fail as the between-treatment differences approach 0. Laska et al.^[58] noted the complexity in interpreting confidence interval estimates obtained by use of Fieller's theorem because this method depends

on whether the individual confidence interval estimate of ΔE excludes 0. It is possible to have inclusion limits for R (R_L, R_U) if the confidence interval for ΔE excludes 0, and exclusion limits of the form “not (R_L, R_U)” if the confidence interval for ΔE includes 0. The condition that the entire 95% confidence interval estimate of the denominator ΔE not include 0 is equivalent to rejection of the null hypothesis that the treatments differ in mean effectiveness at the $\alpha = 0.05$ level. It is also possible to obtain confidence intervals for R that consist of the whole line $(-\infty, \infty)$ if the coefficients of variation for both ΔE and ΔC are large. Wakker and Klaassen^[59] suggest that an estimate of R is useful only when the data are sufficient to allow the conclusion that ΔE is not zero.

Cook and Heyse^[61] proposed a method for estimating R and its 95% confidence interval through an angular transformation. Fig. 1 shows the angular transformation done by using the cost-effectiveness plane.^[62] The slopes of the rays connecting points A and B to the origin are sometimes called the “average cost-effectiveness ratios.” The incremental cost-effectiveness ratio R is simply the slope of the line segment connecting the mean costs (C) and health outcomes (E) for treatments A and B. Redefining the origin of the cost-effectiveness plane to the point (E_A, C_A), θ is simply the angle connecting the $\Delta E > 0$ axis to the A–B line segment. Table 1 shows how θ can be used to facilitate the interpretation of cost-effectiveness ratios.

Values of θ in quadrants II or IV indicate that one of the treatments dominates the other in the sense that one treatment has a greater effect and lower cost. Values of θ in quadrants I or III indicate that the two treatments trade off costs and effects. Use of θ allows a specific interpretation of the relative direction of treatments A and B. The ratio R does not allow a specific interpretation. For example, the ratio cannot distinguish between quadrants II and IV when R is negative and cannot distinguish between quadrants I and III when R is positive. However, the interpretation of the cost-effectiveness of therapy B relative to A depends on the quadrant.

Fig. 1 Cost-effectiveness angle (θ): program B relative to program A

Table 1 Use of θ to Help Interpret Cost-Effectiveness Ratios

Direction of ΔC and ΔE	Range for angle	Quadrant
$\Delta C \geq 0; \Delta E \geq 0$	0–90°	I
$\Delta C \geq 0; \Delta E \leq 0$	90–180°	II
$\Delta C \leq 0; \Delta E \leq 0$	180–270°	III
$\Delta C \leq 0; \Delta E \geq 0$	270–360°	IV

For purposes of estimation, the method uses standardized differences in average cost and effect for the angular transformation. This is given by the equation

$$\theta = \begin{cases} \tan^{-1} \left[\Delta \hat{C} / s_{\Delta \hat{C}}, \Delta \hat{E} / s_{\Delta \hat{E}} \right] & \text{if } \Delta \hat{C} \geq 0 \\ 180 + \tan^{-1} \left[\Delta \hat{C} / s_{\Delta \hat{C}}, \Delta \hat{E} / s_{\Delta \hat{E}} \right] & \text{if } \Delta \hat{C} < 0 \end{cases} \quad (1)$$

where $s_{\Delta \hat{C}}$ and $s_{\Delta \hat{E}}$ are the standard errors of the between-group differences in mean costs and effects. The transformation θ stabilizes the variability of the ratio, especially when the effects are numerically small. The angle θ and its standard error can be estimated by using the jackknife^[63] or the bootstrap.^[64] The grouped jackknife method^[65] may offer some advantages over the bootstrap because it can easily adjust for multiple centers by doing the calculations leaving out one center at a time. Estimates of ratios can be computed by back-transforming from θ to R through Eq. 1.

Net Benefits

Stinnet and Mullahy^[66] proposed an alternate formulation for economic evaluations based on estimating the net monetary (or health) benefits associated with the candidate treatment. The approach is closely related to the incremental cost-effectiveness ratio by starting with the premise that a candidate program will be adopted if $R = (\Delta C / \Delta E)$ is less than a predefined threshold ratio λ . Net monetary benefits, as a function of λ , are expressed by

$$\text{NMB}(\lambda) = \lambda \Delta E - \Delta C$$

in units of cost, and net health benefits are defined equivalently by

$$\text{NHB}(\lambda) = \Delta E - (1 / \lambda) \Delta C$$

in units of health effects. With either formulation, a positive net benefit is supportive for adopting the candidate treatment program. The key to the net benefits approach is the ability to specify λ in order to translate health effects into costs, or vice versa. Many analysts will compute $\text{NMB}(\lambda)$ or $\text{NHB}(\lambda)$ for a broad range of threshold values in a sensitivity analysis. Note that $\text{NMB}(0) = -\Delta C$ provides a relationship with the cost-minimization analysis. Similarly, $\text{NMB}(R) = 0$ relates net monetary benefits and cost-effectiveness analysis.

Heitjan^[67] and Willan and Lin^[68] identified several advantages of the net benefit approach relative to the incremental cost-effectiveness ratio. The advantages are due to the ability to use sample means, variances, and covariances directly to estimate the model parameters of net benefits. This avoids the computational complexities inherent with ratio estimation. Additionally, individual values of NMB or NHB can be computed for each patient in a clinical trial, so that parametric or nonparametric statistical analysis can be readily applied. The net benefit analysis is different from a cost-benefit analysis because the former is derived from the cost-effectiveness ratio. The threshold cost-effectiveness ratio λ is considered the policy-defined trade-off between costs and health effects. In this sense, the net benefits method is also related to the willingness-to-pay method. The cost-benefit analysis involves a monetary valuation of the health effects.

Illustration: Scandinavian Simvastatin Survival Study

The Scandinavian Simvastatin Survival Study (4S) was a randomized, multinational, double-blind, placebo-controlled trial of simvastatin for hypercholesterolemic patients with existing heart disease.^[22] The study consisted of 4444 patients from Denmark ($n = 713$), Finland ($n = 868$), Iceland ($n = 157$), Norway ($n = 1025$), and Sweden ($n = 1681$) who previously had myocardial infarctions or stable angina pectoris. The median duration of patient follow-up was 5.4 years. The study showed that simvastatin was associated with a 30% reduction in the risk for death from any cause ($P = 0.0003$). Data on hospital admissions were prospectively collected to evaluate the effect of simvastatin on health care resource use. Pedersen et al.^[69] reported that patients randomly assigned to simvastatin had 34% fewer hospital days than patients assigned to placebo ($P < 0.0001$).

Other investigators have based formal cost-effectiveness analyses of cholesterol lowering with simvastatin on 4S.^[69,70] It is not our intention to reconsider these evaluations but rather to illustrate the statistical methods. We focus on the cost-effectiveness measure cost per death averted. Costs were assigned to simvastatin use and hospitalization by using Swedish prices converted to U.S. dollars. Simple summaries of the 4S results are given in Table 2. Simvastatin was associated with fewer patient deaths during the trial, but this positive health effect came at additional patient costs. The overall full-sample cost-effectiveness ratio was \$59,201 per additional death averted. Table 3 gives a comparison of several methods for estimating R with 95% confidence intervals. Most of the methods yield similar results because the health effect in this study was substantial. The Taylor series method appears to differ from the others because it provides symmetric limits, which are probably not appropriate for ratios of this type.

Table 2 Summary of Patient Costs and Survival in 4S

	Placebo	Simvastatin	Difference (S – P)
Sample size	2223	2221	
Proportion surviving to end of trial	0.885	0.918	0.033
Average cost/patient	\$3131	\$5098	\$1966

Table 3 Comparison of Methods to Estimate R and 95% CI

Method	Estimate of R	95% Confidence interval
<i>Full sample</i>		
Taylor series	\$59,201	(26,579, 91,824)
Fieller's	\$59,201	(37,369, 126,690)
<i>Bootstrap</i>		
Untransformed	\$63,992	(35,612, 126,819)
Using θ	\$58,146	(35,612, 126,819)
<i>Jackknife using θ</i>		
Grouping by center	\$59,364	(38,968, 116,596)
Stratifying by country	\$62,653	(36,723, 180,691)

R = incremental cost per death averted.

Specifying a threshold cost-effectiveness ratio of $\lambda = \$75,000$ per death avoided, the net monetary benefit is 524.7 with 95% confidence interval (– 826.3, 1875.7). The positive point estimate of the NMB indicates a favorable trade-off of net costs and net health effects. However, because the 95% confidence interval covers zero this estimated NMB did not attain a level of statistical significance at the $\alpha = 0.05$ level. Fig. 2 shows a graph of the NMB and the 95% confidence interval for a broad range of threshold values λ . The sample cost-effectiveness ratio

Fig. 2 Net monetary benefit (NMB) and 95% confidence intervals for a range of threshold values λ

Fig. 3 Ninety-five percent confidence intervals for the incremental cost per additional survivor in the Scandinavian Simvastatin Survival Study by country and for the overall country average. CE = cost-effectiveness

can be picked off the graph as the value of λ where the NMB crosses the horizontal axis. Also note that the 95% confidence interval estimate of the cost-effectiveness ratio using Feiller's theorem can be derived as the values of λ where the upper and lower bound estimates of NMB cross the horizontal axis. This important relationship between the net benefits method and the cost-effectiveness ratio was derived by Heitjan.^[67]

Recall that 4S was a multinational study. Because of the potential for large variability among countries in the utilization and cost of health care resources, the appropriateness of combining economic data across the countries should be assessed. Cook et al.^[71] provided a test for homogeneity of the individual country ratios that can be used in this case. Fig. 3 shows the individual cost-effectiveness ratio estimates per country from 4S and the 95% confidence intervals. These ratios appear to be homogeneous ($P = 0.73$), justifying the appropriateness of the overall pooled ratio estimate given in Fig. 3 and Table 3.

INTERPRETING THE RESULTS

Drawing conclusions from the results of cost-effectiveness analyses can also be complex because doing so usually involves some evaluation of the trade-offs between costs and health outcomes. The exception would be therapies that are associated with both lower costs and greater health outcomes. These therapies are said to dominate the comparator therapy, and interpreting the results in these cases is straightforward when a cost-consequences analysis is used. However, most evaluations will need to compare programs that favor one on cost and the other on effectiveness. In these cases, the analyst needs to base a conclusion on the magnitude of the incremental cost-effectiveness ratio. One method proposed by Laupacis et al.^[72] for Canada was to classify technologies into one of five grades for recommendation on the basis of their incremental cost per QALY gained. The authors did acknowledge, however, that

cost-effectiveness should not be the sole basis on which to recommend the acceptance of a new therapy.

Another method often used in published studies compares the cost-effectiveness ratio for the therapy under study to ratios for a broad range of well-accepted medical therapies. For example, Johannesson et al.^[70] reported that the cost per life-year gained in patients with coronary heart disease who received simvastatin therapy ranged from \$3800 for 70-year-old men with total cholesterol levels of 309 mg/dl to \$27,400 for 35-year-old women with total cholesterol levels of 213 mg/dl. The authors concluded that the ratios were well within the range that was considered cost-effective in other studies. Rankings of the cost per life-year or cost per QALY gained for a broad range of therapies, referred to as “league tables,” have been published.^[73] League tables should be interpreted with caution because the methods used for the individual evaluations may be very different.

Bayesian Statistical Inference

It is widely recognized by economists and statisticians that simple point estimates of the mean costs and benefits are not adequate to describe the results of economic evaluations.^[74] Most of the available methods provide confidence interval estimates of the means, or ratios of the means, by incorporating estimates of variability into the evaluation. Other classic methods of statistical inference using formal hypothesis testing may have limitations when applied to studies with inadequate power to detect meaningful differences. Jones^[75] argued for the use of formal Bayesian methods that elicit prior beliefs by using expert opinion. Luce and Claxton^[76] recommended the use of decision-analytic models as essentially an informal application of Bayesian reasoning. Their proposal was to combine experimental and nonexperimental data with expert opinion as the basis for evaluating medical technologies.

Some evaluations are beginning to apply empirical Bayes methods to cost-effectiveness analysis. Jones^[77] recommended reporting the estimated probability distribution function for the economic variable of interest to enable the user to make a more informed interpretation about the uncertainty in the estimate. Other forms of analysis may simply estimate the probability that the cost-effectiveness ratio falls within each of the four quadrants of the cost-effectiveness plane. Heitjan et al.^[78] used simulated random draws from the estimated posterior distributions of cost and effectiveness parameters to tabulate the probabilities that the cost-effectiveness ratio falls within several important areas of the cost-effectiveness plane. One useful graphical display for summarizing the results of a cost-effectiveness analysis is the cost-effectiveness acceptability curve proposed by van Hout et al.^[79] The curve provides an estimate of the probability (plotted on the Y-axis) that the cost-effectiveness ratio for a candidate therapy is favorable with respect to a target ratio R (plotted on the X-axis). Their method assumes that costs and benefits are bivariate normal and uses point estimates of the variables to integrate over the region of the cost-effectiveness plane that gives ratios as favorable as R . A different computational method that does not make any distributional assumptions is a simple probability plot based on the number of bootstrap resampled cost-effectiveness ratios that are as favorable as R . This nonparametric method was applied to the 4S data, and the resulting cost-effectiveness acceptability curve is shown in Fig. 4. For example, Fig. 4 could be used to show that there is greater than a 90% probability that simvastatin therapy is associated with a cost-effectiveness ratio at least as favorable as \$100,000 per death avoided. Alternatively, there is greater than a 90% probability that the net monetary benefits are positive for a threshold of \$110,000 per death avoided. Results of this type are of interest to decision makers who may establish policy on the basis of the magnitude of estimated cost-effectiveness ratios.

Fig. 4 Cost-effectiveness (CE) acceptability curve in the Scandinavian Simvastatin Survival Study. The graph plots the probability that for simvastatin, the cost per additional survival would be deemed acceptable for a range of cost-effectiveness ratio thresholds

CONCLUSION

The concern over the costs of health care will continue to grow as more novel health care technologies become available to a growing elderly population. In this environment, health care providers will attempt to identify and apply treatment programs that offer the greatest benefit for the fixed level of investment in health care. Formal economic evaluations will be looked on to help guide these decisions. Pharmaceutical companies will need to significantly enhance their clinical development programs to address the needs of the changing marketplace. More emphasis will be placed on studies of patient outcomes, including quality of life and cost-effectiveness, much earlier in the product development program. Moreover, as guidelines and formal requirements for cost-effectiveness analysis are put in place, there will be a growing need to assemble specific documentation of the socioeconomic impact of the candidate product. This information would also be helpful in marketing new products to sophisticated managed care organizations. Drummond and McGuire^[45] provided a contemporary textbook that describes the available methods to integrate utilization, cost, and outcome data within an appropriate theory of economic evaluation.

Statisticians working in the pharmaceutical industry will need to address the complexities that these changes will bring to the development program. There will be a shift away from formal hypothesis testing to methods of estimation, including the use of statistical models to help identify the best uses of the candidate therapies. There will also be opportunities to work on data sources outside of the clinical program to provide the most comprehensive evaluation for the product.

Pharmacoeconomics: Cost-Effectiveness Analysis

Shahram Heshmat

Department of Public Health, University of Illinois at Springfield, Springfield, Illinois, U.S.A.

Abstract

The purpose of this entry is to discuss the concept of cost-effective analysis for the evaluation of health services, and to familiarize readers with how to interpret CEA results.

Keywords: Cost-effectiveness; Health services; Resource allocation.

INTRODUCTION

As resources have become scarcer and public accountability has become greater, health care providers have been forced to reexamine the costs and the benefits of its activities as a step in enhancing their abilities to allocate resources more effectively. Cost-effectiveness analysis (CEA) provides health professionals with basic tools to ensure appropriate resource allocation among competing demands. The purpose of this article is to discuss the concept of CEA for the evaluation of health services, and to familiarize readers with how to interpret CEA results.

TYPES OF ECONOMIC EVALUATION

Economic evaluation provides health professionals with basic tools to ensure appropriate resource allocation among competing demands. Economic evaluation is a subfield within economics that has explored the question of how to maximize consumer welfare within a limited budget. Given the scarcity of resources, every decision to use public health resources requires to examine the costs and the benefits of those decisions. From an economic perspective, an efficient allocation of society's limited resources requires the benefits of an intervention to exceed the costs. This means the valuation people place on those programs is greater than the cost of producing them. The basic task of economic evaluation involves a comparison of the costs and benefits of adopting program A rather program B (or simply status quo).

Economic evaluation includes cost-minimization, cost-effectiveness analysis (CEA), cost-utility analysis (CUA), and cost-benefit analysis (CBA) studies. There is substantial overlap between these four types of cost evaluation. Each characterizes costs in the same terms, but differs with respect to outcome measures (the benefits of health intervention).

In cost-minimization analysis, the effectiveness of the interventions is assumed or has been shown to be the same, and only the cost difference in the interventions is determined. A cost-minimization analysis address the question of which alternative is least cost given that they are equally effective.

Cost-effectiveness and cost-benefit analyses are formal methods for comparing the benefits and costs of a medical intervention in order to determine whether it is worth doing. The only difference between the two is that CEA measures benefits in terms of some standard of clinical outcome or effectiveness, such as mortality rates, years of added life, or quality-adjusted life years. CEA usually is based on a one-dimensional measure of health outcome (e.g., reductions in blood pressure or premature births averted). In CBA, all benefits are converted into monetary values which allow compare health-related programs with other types of programs or policies. The underlying goal of CEA/CBA analyses is to find which alternative provides maximum aggregate health benefits for a given level of resources or, equivalently, which alternative provides a given level of health benefits at the lowest cost. CEA is most suitable when comparing interventions that have similar health outcomes.

Cost-utility analysis (CUA) is a subset of CEA studies. Cost-effectiveness and cost-utility analysis are identical except that the effectiveness measure used in a cost-utility analysis is one that reflects societal or individual preferences for the outcome. Cost-utility analysis (CUA) is a broader form of analysis than cost-effectiveness analysis. CUA seeks to collapse multi-dimensional consequences of health status (i.e., degrees of disability) into a one-dimensional metric (e.g., Quality-Adjusted Life Years). The consequences of programs are measured in time units adjusted by health utility weights. That is, states of health associated with the outcomes are valued relative to one another. In general terms this means that one can assess the quality of (for example) life-years gained, not just the crude number

of years. This approach is particularly useful for those health treatments that extend life only at the expense of side effects or that produce reductions in morbidity rather than mortality. Gold et al.^[1] do not distinguish between cost-utility analysis and cost-effectiveness analysis.

Another type of economic evaluation study is the cost-of-illness (COI) study. The goal of COI study is to estimate the total societal costs of caring for persons with an illness compared with persons without the illness. The result of a cost-of-illness study can be used as input to a formal cost-effectiveness analysis.

WHAT IS COST-EFFECTIVENESS ANALYSIS?

The basic tasks of CEA are to identify, measure, value, and compare the costs and consequences of the alternatives being considered.^[2] The central purpose of CEA is to compare the relative values of different interventions in creating better health and longer life. The results of such evaluations are typically summarized in a cost-effectiveness ratio (*C/E*), where the denominator reflects the gain in health from a candidate intervention (measured, e.g., in terms of years of life gained, premature births averted) and the numerator reflects the cost of obtaining that health gains. The cost-effectiveness ratio [dollars per life-year (LY)] serves as a yardstick for measuring the relative priority of health interventions that compete for limited resources. The underlying rationale for CEA is to try and maximize the health effects for a given amount of resources.^[2]

In CEA, the consequences of programs are measured in the most appropriate natural or physical units, such as “years of life gained” or “cases correctly diagnosed.” Health outcomes can range from intermediate outcomes, such as millimeters-of-mercury blood pressure reduction or disability days averted, to more distal outcomes such as lives saved, life-years gained, or quality-adjusted life-years (QALYs) gained, or “cases correctly diagnosed.” A QALY is the equivalent of one year of life in full health. To estimate the relative cost-effectiveness of various services, CEA requires some common unit of measurement to help compare programs. QALY has been used historically in studies to assess the relative value of different interventions, with each intervention carrying a “price tag” or a rough estimate of the cost to save a comparable year of life. For example, childhood immunizations and smoking cessation cost less than \$5,000 per QALY gained. The amount here can be considered as a purchasing price for one QALY. An intervention is “cost-saving” if it reduces costs while improving health.

The QALYs (pronounced “qualy”), or analogous measure, is the most comprehensive measure of outcome used in CEA, incorporating both quality and survival information.^[1] The purpose of QALYs is to measure in a single figure the impact of an intervention that increases both

quantity and quality of life. This measure assumes that different states of illness can be assessed in terms of utility patients provide relative to perfect health over a period of one year.

Quality weights can be elicited from professionals with expertise in the condition and intervention, from patients with the condition, or from the general public.^[3] The concept of the quality-adjusted life-year is explicit recognition that there are states of health for which people are willing to take a measurable risk of a bad outcome (usually death) to avoid.^[4] A common method to elicit people’s utility is to describe medical condition (e.g., being a diabetic) and ask them to choose between ten years in that condition or some smaller number of years without it. If they respond that they would choose five years of perfect health life over ten years with diabetes, then they are assessing life with the illness as half as good as diabetic life. A simpler approach that avoids assigning utility values to ill health is to look only at the life years (LYs) saved by an interventions. Evidence suggests that in many policy interventions QALYs and LYs provide similar rankings.

The quality weights are usually measured in a scale that extends from 0 (death) to 1 (perfect health). An intervention that extends a person’s life for one year and provides perfect health generates 1 QALY. In contrast, an intervention that extends a person’s life for one year but at a diminished quality of life, with a value of 50%, produces half as much benefit, or 0.5 QALY. An intervention that does not extend a person’s life but improves quality of life from 0.50 to 0.75 produces 0.25 QALY per year. Consider, for example, an illness such as diabetes that reduces one’s quality of life by 40%, so the person’s QALY over the year would be 0.60. Thus, an intervention that would prevent such an illness would yield 0.40 QALYs. If the intervention saved a million people from having the diabetes every year this would amount to 400,000 QALYs per year. If the intervention cost \$100 million, and an alternative investment of \$100 million into, say, safer airline travel saved 500 QALYs per year, then the current illness prevention can be said to be more cost-effective.

CEA incorporate preferences for receiving health-care benefits that occur now rather than later. People value a year of good health now more highly than a year of good health in ten year’s time, so a policy to reduce an illness today might be valued more than an intervention to reduce, say, risk of heart disease, in the distant future. Thus, allowance needs to be made for the differential timing of costs and consequences. Economists call this the notion of time preference. Discounting is more controversial, however, when it is applied to health effects. The assumption implicit in discounting implies that health effects gained in the future are less valuable than health effects gained today. For example, is it less valuable to avert a heart attack ten years from now than a heart attack next year, and do they have the same impact on health-related quality of life and on life expectancy? Economists who work on CEA

have long accepted that health effects should be discounted in the same way that the dollar expenditures are and that the same discount rate should be used. Something like 3% is typical for government projects. If the interest rate is 5%, for example, the present value of \$1 to be obtained in one year is about \$.97—if you invest \$.97 today, you will have \$1 in one year, so \$.97 accurately reflects the present value if \$1 in one year. With a higher interest rate, the present value is lower because the opportunity costs involved in waiting to get the dollar are greater.

In CEA, the added costs and health outcomes associated with a program are used to calculate the incremental cost-effectiveness ratio relative to some comparator. No attempt is made to value the consequences, so it is implicitly assumed that the output concerned is in some sense “worth having.” Although in CEA, the economic valuation of health consequences is avoided, the problem of deciding in absolute terms whether a program is worth funding rests on whether a particular value of the cost-effectiveness ratio (e.g., \$50,000 per QALY) is acceptable.

Valuing human life is a necessary part of any economic evaluation. The most common approach is to calculate the value of a generic human life. The value is revealed from individual behavior. It is the answer to the question of “how much are you willing to pay to reduce the risk to your life?” People make risk-money tradeoff decisions on a daily basis. For example, how much people are willing to pay for airbags in cars and other safety features? Suppose that there is a 1 in 100,000 chance that an airbag in your car will save your life, and that you are willing to pay \$50 for an airbag to reduce the risk by 1 in 100,000. This implies that the airbag (intervention) would save, statistically, one life. This implies that the value of the one life saved is $50 \times 100,000 = \$5$ million (C/E or $\$50/0.00001$).

The incorporation of measures of quality of life into decision making about allocation of resources is a cornerstone of the outcome movement. In theory, CEA enables decision-makers to compare how much benefit patients are receiving from seemingly incomparable health services.^[2] Decision-makers may be federal, state, or local. They may be in the private sector or in the public sector. If a moderately expensive treatment brings benefits, CEA can show whether it is more cost-effective than a slightly expensive treatment that brings modest benefits. It makes allocation tradeoffs explicit; for example, if a health insurance company reimburses for Pap smears every three years instead of yearly, CEA can estimate how much money it will save and how many lives of enrollees will be lost. Cost-effectiveness analysis teaches us that after we spend money to achieve important benefits, further benefits often come at greater and greater financial cost. For example, an early CEA showed that an inexpensive screening test for colon cancer, if repeated for a sixth time in a patient whose first five tests were normal, continued to find colon cancer, but at a cost of \$26 million for every year of life gained.^[5]

KEY CONCEPTS IN PERFORMING COST-EFFECTIVENESS ANALYSIS

Cost-effectiveness analysis depends on the perspective of the decision-maker. Specifically, a program or intervention may be deemed to be cost-effective from the standpoint of the individual patient or from the standpoint of a specific inpatient service. However, the same program or intervention may not be cost-effective when viewed and assessed from the overall societal point of view. Analyses based on different perspectives cannot be compared because, reflecting the interests associated with each perspective, they count different health effects and resources and value them differently. Most published studies in the medical literature tend to evaluate cost-effectiveness from the perspective of society as a whole and thereby generally define cost-effectiveness in terms of dollars or resource spent per year of life saved. The appropriate perspective depends on the objective of the study. It should be noted that from the perspective of the comprehensive societal viewpoint, all costs and effects are considered no matter who pays the costs or who receives the effects. Such comprehensive information is necessary to support decision-makers who want to consider the impact of their decisions on all affected parties.

In order to compare the desirability of programs, the CEA ratios must be based on comparable definitions of cost and outcome. A problem in comparing programs' costs is that studies may differ in the types of cost they include in the numerator of the CEA ratio. For example, the value of time that patients spend in obtaining care or the value of the reduction in work loss because of health improvement is often excluded from CEA. Inclusion/exclusion may have a substantial effect on the cost-effectiveness ratio.

The basic approach is to measure all relevant costs and benefits and to determine the ratio between the two. All other things being equal, an alternative with a lowest cost-benefit ratio (whether benefits are measured in terms of dollars or some other metric) is preferable to an alternative with a higher cost-benefit ratio. However, in the case of mutually exclusive interventions, for example, surgery or drugs but never both, the issue is whether the additional improvement in benefits is worth the additional cost. In such cases, incremental cost-effectiveness or cost-benefit analysis is required.

The panel on CEA in Health and Medicine of the U.S. Public Service^[2] emphasized the importance of conduct of a “reference case” analysis. The reference case analysis is an analysis that is performed according to the standard set of rules. The reference case analysis allows comparison with other cost-effectiveness analyses performed using the same set of rules. This greatly enhances the usefulness of information to policymakers. In the reference case, analysis is performed from the societal perspective.

ALTERNATIVES

Cost-effectiveness analysis requires the specification of two or more alternatives (or programs). By definition, assessment of CEA is a relative phenomenon, and thus the calculation of a single cost-effectiveness measure, that is, cost-effectiveness ratio, provides little, if any, quantitative insight regarding joint clinical and economic impact. For example, if a hospital is considering an expansion of its intensive care facilities, it may perform a study that assesses the cost-effectiveness of two viable alternatives—the expansion of the current intensive care unit (ICU) from 10 to 15 beds or the construction of a new 10-bed intermediate care.

The choice of alternatives (comparators) can make an enormous difference in the cost-effectiveness of an intervention because the elements in a cost-effectiveness ratio are calculated as differences between two alternatives. The numerator of the ratio, net costs, is the difference in costs between the intervention and the comparator. The denominator, net health effects, is the difference in health effects between the two. For example, when annual Pap smears are compared to no screening, they cost about \$40,000 per life-year saved (1985 dollars). But compared with the more realistic alternative of screening every two years, the cost per life-year is more than \$1 million.^[6]

Alternatives are either independent or mutually exclusive programs. Two programs, A and B, are defined as independent if the costs and effectiveness of program A (B) are not affected by whether program B (A) is implemented or not. The two programs are viewed as applying to two different populations, for example, the treatment of ulcer patients and the treatment of arthritis patients.

Cost-effectiveness analysis may include mutually exclusive programs with different applications of the same medical intervention or drug, such as drug regimens, or different levels of a program, such as drug dosage. For example, cholesterol reduction in persons with different cholesterol levels could be regarded as different programs that compete for resources, and cost-effectiveness would be different in each group. In the case of competing mutually exclusive alternatives for the same patients, the appropriate analysis would be based on incremental cost-effectiveness analysis.

AVERAGE RATIO VERSUS INCREMENTAL RATIO

An average cost-effectiveness ratio and an incremental or marginal cost-effectiveness ratio are different concepts.^[7] An average cost-effectiveness ratio is estimated by dividing the cost of the intervention by the effectiveness of the intervention compared to “doing nothing.” An incremental or marginal cost-effectiveness ratio is an

estimate of the cost per unit of effectiveness of switching from one intervention to another. If only one program is compared with doing nothing, then the incremental cost-effectiveness ratio will be the same as the average cost-effectiveness ratio. Furthermore, explicit declaration of doing nothing as the alternative intervention helps to frame discussion of the desirability of the intervention.

In estimating an incremental or marginal cost-effectiveness ratio, both the numerator and denominator of the ratio represent differences between the alternative interventions.

$$\text{Difference in cost/Difference in effectiveness} = (C_1 - C_2) / (E_1 - E_2)$$

Where

Difference in cost = cost of intervention (C_1)—Cost of alternative (C_2)

And

Difference in effectiveness = Effectiveness of the intervention (E_1)—Effectiveness of the alternative (E_2)

For example, if a treatment A cost \$50,000, and its average effects in patients with the disease is to add 2.5 QALYs, the average cost-effectiveness ratio of the intervention A would be \$50,000/2.5, or \$20,000 per QALY. The incremental cost-effectiveness of the intervention A compared with the alternative, doing nothing, is also \$20,000 because

$$(C_1 - C_2) / (E_1 - E_2) = (\$100,000 - 0) / (3.5 \text{ QALY} - 0 \text{ QALY})$$

Cost-effectiveness analysis is based on the solution to a simple optimization problem. Given a budget constraint, an explicit objective such as QALYs, and a set of alternative programs, such as treatments, that use resources (cost C_i) and contribute to the objective (effectiveness E_i), the optimal resource allocation is to rank order the programs according to their cost-effectiveness ratios (C_i/E_i) and to select them from lowest to highest to the point where the resource budget is exhausted. This allocation can be shown to yield the maximum total effectiveness, i.e., QALYs gained, subject to the budget constraint.^{[1,8]a}

The following examples^b illustrate the decision rules based on CEA for resource allocation decisions that can be used to maximize the health effects for a fixed budget. The fixed budget used to maximize the health effects will also implicitly yield a price per unit of health effects on the margin. We start with independent programs.

^aThe optimization rule is based on the assumption of divisibility of programs with constant returns to scale, but violations of this assumption are to be expected in practice.

^bThese examples are adapted from Refs. [1,8].

Independent Programs

The decision rule for CEA of independent programs is that they should be ranked from most to least *C/E* ratios. Services that bring large benefits at small cost would be at the top of the list, and those that bring few benefits at high cost would be at the bottom. With a fixed budget, programs should then be implemented in order of their *C/E* ratios until the budget is exhausted.

Assume that the health department in a large metropolitan area has been given a budget of \$500,000 to spend on three different independent health programs, that is, three health programs for three different patient groups. Assume further that each program is the only one available for that patient group so that the three programs are compared with doing nothing for each patient group. This implies that for each program, the average and incremental cost-effectiveness ratios are the same for each patient group. The objective is to save the greatest aggregate number of life-years.

The costs and effects (in terms of life-years gained) of each program are shown in Table 1, where the programs have also been ranked according to their *C/E* ratios. The cost of program A is \$100,000 and the number of life-years gained per patient is 50, yielding a cost-effectiveness ratio of \$2,000, and so on. These cost-effectiveness ratios can be viewed as a ranking of the different programs in terms of their desirability; that is, it is possible to say that program A should be given priority over program C because it has a lower cost-effectiveness ratio. The optimal allocation of the \$500,000 budget is to fund program programs A, B, and C, up to a cutoff of \$6000/LY. The total of 130 LYs saved is the most possible.

In general, the size of budget or the choice of a critical, or cutoff, value of the cost-effectiveness ratio will determine which of the available programs should be implemented. For example, if we have a budget of \$120,000, only program A will be adopted because this program will maximize the effects for the given budget. If the budget increases to \$320,000, both programs A and B will be adopted because this maximizes the effectiveness for the budget. Finally, if the budget increases further to \$500,000, programs A, B, and C will be funded. The decision rule is thus to start implementing the program with the lowest cost-effectiveness ratio and then to add additional programs according to their cost-effectiveness ratios until the budget is exhausted.

Table 1 Example of Three Independent Programs

Programs	Cost	Life-years	<i>C/E</i>
A	\$120,000	50	\$2,400
B	\$200,000	50	\$4,000
C	\$180,000	30	\$6,000
D	\$200,000	25	\$8,000

Note also that the different budgets yield an implicit price that we are willing to pay per life-year gained on the margin. For instance, if a budget of \$120,000 is used, this implies that we are willing to pay \$2,400 per life-year gained on the margin. It is the price we are paying per life-year gained for the program with the highest cost-effectiveness ratio that is implemented. If a budget of \$500,000 is used, this implies that we are willing to pay \$6,000 per life-year gained on the margin. Thus the cost-effectiveness cutoff in this example is \$6,000/LY if the budget is \$500,000. This means that if a new program is added to the menu, it should be adopted only if its cost-effectiveness ratio is less than \$6,000. With a limited budget, the cost that appears in the numerator of the *C/E* ratio of a program is the net burden of the program on the budget.

A classic example of CEA is the experience of Oregon's attempt to ration medical benefit with its limited Medicaid budget.^[5] The plan was simple. The legislature appointed a commission to rank Medicaid services from the least cost-effective. Services that bring large benefits at small cost would be at the top of the list, and those that bring few benefits at high cost would be at the bottom. The state would then estimate the cost of providing each service to an expanded number of Medicaid beneficiaries, starting at the top of the list and moving down until the money ran out. At that point, it would draw a line and all services below the line would no longer be reimbursed by the Medicaid program. By refusing to pay for services that are not very cost-effective, the state would save money, enabling it to add extra people to Medicaid. In this case, cost-effectiveness analysis shows how to maximize health benefits within a specific health-care budget. By specifying its Medicaid budget and the number of people that would be covered, Oregon could determine which services it could afford. Thus it would, in theory, show how to buy the greatest amount of medical benefits with its Medicaid dollars.

Mutually Exclusive Programs

Often, applications of CEA in health care involve comparisons among competing alternatives for the same condition, or the appropriate intensity of an intervention or the appropriate groups to receive it, for example, alternative drug dosages for a given condition, or comparisons between drugs and surgical treatment. In such competing choice situations, the basic CEA decision rule needs to be modified to incorporate the possibility of mutually exclusive programs for the same condition. This section considers the decision rules for mutually exclusive programs. Similar to the independent programs, a fixed budget can be used as the decision rule to decide which program should be implemented.

For the mutually exclusive programs, the first step is to order the programs according to their effectiveness. The next step is to calculate the incremental *C/E* ratios. Then, dominated alternatives should be excluded. The

Table 2 Four Mutually Exclusive Programs

Programs	Cost	Benefits (LYs)	Average <i>C/E</i>	Incremental <i>C/E</i>	Without program C
A	\$50,000	10	\$5,000	\$5,000	\$5,000
B	\$200,000	20	\$10,000	\$15,000	\$15,000
C	\$900,000	30	\$30,000	\$70,000	–
D	\$1000,000	40	\$25,000	\$10,000	\$40,000

incremental *C/E* ratios should then be recalculated without the dominated alternatives being included. This process continues until a number of programs with increasing incremental *C/E* ratios remain. With a fixed budget, we then start by considering the least effective program, and then continuously switch patients to more effective programs until the budget is exhausted.

Assume that there are four different alternative programs (e.g., four different cholesterol-lowering drugs) for treating patient groups. The costs and effects are shown in Table 2. Because the four programs are mutually exclusive, it is only possible to carry out one of the programs for each patient group. The first column in Table 2 shows the costs; the second column shows the effects; the third column shows the average *C/E* ratios, which compares each program to the status quo baseline alternative. Note that the average cost-effectiveness ratios are misleading and should not be used as a decision rule.

The correct analysis examines the incremental cost of program B relative to A, and so on, as well as its incremental benefit. For program A, the incremental *C/E* ratio is equal to the costs of A compared to doing nothing divided by the effects of A compared to doing nothing, which gives an incremental cost-effectiveness ratio of \$5,000. This is the same as the average *C/E* ratio for A because it is the least effective program.

For B, the incremental *C/E* ratio is equal to the costs of B minus the costs of A (\$200,000 – \$50,000 = \$150,000) divided by the effects of B minus the effects of A (20 – 10 = 10), which gives an incremental *C/E* ratio of \$15,000 (150,000/10). For C, the incremental cost-effectiveness ratio is equal to the costs of C minus the costs of B (900,000 – 200,000 = 700,000) divided by the effects of C minus the effects of B (30 – 20 = 10), which gives an incremental cost-effectiveness ratio of \$70,000 (700,000/10). For D, the incremental *C/E* ratio is equal to the cost of D minus the costs of C (1000,000 – 900,000 = 100,000) divided by the effects of D minus the effects of C (40 – 30 = 10), which gives an incremental *C/E* ratio of \$10,000 (100,000/10).

The next step is to exclude dominated alternative. A program is dominated if the incremental *C/E* ratio decreases for the next program with higher effectiveness (it yields fewer health benefits for the same amount of money). The reason for excluding the dominated alternative is that irrespective of the size of the budget, more units of effectiveness are always gained by doing the more effective program.

In this example, program C is dominated because the incremental *C/E* ratio for D decreases. Therefore, program C should be excluded from further consideration. After C has been excluded, the incremental *C/E* ratios should be recalculated. The incremental *C/E* ratios for A and B will be the same as before, but the incremental *C/E* ratio for D will change. For D, the incremental *C/E* ratio is now equal to the costs of D minus the costs of B (1000,000 – 200,000 = 800,000) divided by the effects of D minus the effects of B (40 – 20 = 20), which gives an incremental cost-effectiveness ratio of \$40,000 (800,000/20).

The incremental *C/E* ratios show the implied price per life-year gained from implementing the different programs. The ratios cannot, however, be used to rank the programs because without knowing the size of the budget or the price per life-year gained that society is willing to pay, it is impossible to know which of the four mutually exclusive programs should be implemented.

With a fixed budget, the decision rule is to start by considering the program with the lowest incremental *C/E* ratio, and then switch patients to continuously more effective programs until the budget is exhausted. Table 3 shows the program choice for different budget sizes. Because the programs are mutually exclusive, each patient can only receive one of the programs. This means that as the budget increases, we will switch from a less effective program to a more effective program.

For a budget of \$50,000, program A will be implemented. If all patients are treated with program A, all the budget of \$50,000 will be exhausted, so it is not possible to switch any patients to more effective treatments. If the budget is above \$50,000, we can start to switch patients from treatment A to B. If the budget is \$200,000, we will be able to switch all the patients to program B. Finally, if the budget exceeds \$200,000, we can continue to switch patients from program B to program D.

Table 3 The Choice of Mutually Exclusive Program for Different Sizes of the Budget

Budget	Choice of program
50,000	A
200,000	B
1,000,000	D

If the budget is \$1 million or greater, all the patients will receive the most effective treatment, D.

The different budgets also implicitly yield the price we are willing to pay for extra life-years gained. For example, for a budget of \$200,000, the implied price per life-year gained on the margin is \$15,000, that is, the incremental *C/E* ratio for program B. This criterion for judging the acceptability of a *C/E* ratio is known as the shadow price of an explicit budget constraint. The shadow price or the *C/E* ratio of the marginal program represents the opportunity cost of diverting resources to fund a new program. Therefore any new program that competes for resources must have a *C/E* ratio of \$15,000/LY or less to allow a reallocation of resources to the new program to result in a gain of life-years. The criterion would, of course, change as the budget expands, higher *C/E* ratios become acceptable, and vice versa as the budget decreases.

To illustrate the principle of incremental cost-effectiveness analysis, consider the study by Goldman et al.^[9] They evaluated alternative doses of the drug lovastatin for cholesterol reduction in patients who have had a heart attack. The drug has been shown to reduce serum cholesterol, and the amount of cholesterol reduction increases with increasing dose. The benefits are reduced mortality and cost from heart disease. Cost-effectiveness of dosages of 20, 40, and 80 mg are considered among patients with cholesterol levels of at least 250 mg/dl who had suffered a previous heart attack. Table 4 shows a sample of their results. The model calculated present values of net medical cost and life-years for the U.S. population over the period from 1990 to 2015.

Note that one could be easily misled by using the average *C/E* for the 80-mg dose, which is \$25,800. However, the correct measure of its cost-effectiveness is \$84,300, its incremental cost per life-year compared to the lower dose.

Cost-effectiveness information often highlights the counterintuitive high cost of some seemingly inexpensive medical services. Imagine that we offer a \$1,000 screening test to a group of 2,000 people at a total cost of \$2 million. The test saves 100 lives, at a cost of \$20,000 (\$2 million/100) per life saved. This seems like a bargain. What society would not want to spend \$20,000 to save someone's life, or \$2 million to save 100 lives? But what

if an alternative screening test was available that was half as expensive and would save 99 lives? According to CEA, the existence of this less-expensive test radically alters the cost-effectiveness of the first test. As we have seen, the first test costs \$2 million; the alternative test costs only \$1 million. The first test saves 100 lives and the second saves 99. Thus the real cost-effectiveness of the first test is not \$20,000 per life saved, but \$1 million per life saved. We have to increase spending from \$1 million to \$2 million to save one additional life. The pitfall in economic evaluation is failure to acknowledge the existence of less-expensive, although somewhat less beneficial, options in evaluating the *C/E* of a program. After all, any option can be made to look cost-effective if it is compared to a sufficiently less *C/E* alternative.^[5]

CONCLUSION

Although *C/E* is but one element of public decisions about health care, gaining a clearer quantitative understanding of this important element cannot help but improve decision processes. Resource allocation decisions can never be shaped by the mechanical ranking of cost-effectiveness ratios. Ratios provide information about one type of "value," health benefit per dollar spent. But other values of society, including considerations of distributive justice and fairness (e.g., giving priority at times to the sickest of individuals), require that CEA be viewed as an informer of decision making rather than a decision maker per se.^[6] For example, sex education and the distribution of condoms in public school have raised a range of concerns reflecting conflicting social values involving students, parents, educators, and public health officials. The economic evidence must be combined with an understanding of preferences and values of the stakeholders that are not intrinsically technical.

In the face of increasingly limited resources CEA provides opportunities for more efficient delivery of health care. The challenge would be restructure the system in a fashion to create incentives that encourage the appropriate delivery of efficient interventions.^[10]

Phase I Cancer Clinical Trials

Seung-Ho Kang

Ewha Womans University, Seoul, Korea

Chul Ahn

University of Texas Medical School, Houston, Texas, U.S.A.

Abstract

In phase I cancer clinical trials, the subjects are extremely ill patients with cancer who will often be at very high risk of death in the short term under all standard therapies. This entry reviews some of the traditional methods and designs of phase I cancer clinical trials as well as reassessment methods.

INTRODUCTION

The phase I clinical trials represent the first time drugs are given to man and are mainly carried out to establish human toleration. In many phase I clinical trials, the subjects are healthy adult volunteers, while in phase I cancer clinical trials, the subjects are extremely ill patients with cancer who will often be at very high risk of death in the short term under all standard therapies. The design and statistical analysis of the phase I cancer clinical trials are different from those of the other phase I clinical trials. More research into the design and statistical analysis of the phase I cancer clinical trials has been conducted than that of the other phase I clinical trials. Therefore the phase I clinical trials are often used to represent the phase I cancer clinical trials among statisticians.^[1] Here we review only the phase I cancer clinical trials.

The primary aim of the phase I cancer clinical trials is to determine the maximum tolerated dose (MTD) of a new drug, which will be used as a recommended dose level for experimentation in phases II and III cancer clinical trials. In most cancer therapy, toxicity is a prerequisite for optimal antitumor activity. Hence one must endure some degree of treatment-related toxic reaction if patients are to have a reasonable chance of favorable response. Because higher doses are associated with both greater therapeutic benefits and an increased probability of severe toxic reaction, an anticancer drug should be administered at the maximum dose that cancer patients can tolerate. Consequently, the goal of a cancer phase I trial is to determine the highest dose associated with an acceptable level of toxicity, which is often called the maximum tolerated dose (MTD).

Perhaps the two most serious problems currently facing phase I cancer clinical trials are the limited sample size and the ethical concerns. Usually, the total number of patients entered is quite small (such as 20 to 30), and there may be considerable heterogeneity in the patients' health status at entry despite the establishment of entry criteria. It makes it

hard for biostatisticians to find the best design and analysis procedure which are usually evaluated by large sample theory. In contrast to other phase I trials, cancer phase I trials also have a therapeutic aim. Typically, participants in cancer phase I trials are patients at advanced disease stages who consent to participate in the trial only as a last resort in seeking cure. One should design cancer phase I trials to minimize both the number of patients treated at low, nontherapeutic doses as well as the number given severely toxic overdoses.

THE TRADITIONAL METHODS

Although the traditional designs are shown to have poor operating characteristics compared with the continual reassessment method,^[2–6] in practice, the traditional designs still predominate in phase I designs. The primary reasons seem to be that (1) the method is easy to describe and does not require a statistician to design or evaluate and (2) no modeling is required beyond an assumption that the dose–toxicity relationship is nondecreasing. The traditional designs are as follows.

A precise definition of the dose-limiting toxicity (DLT), an occurrence of unacceptable toxicity, is provided in the protocol. The recommendation for grading toxicity is given, for example, in.^[7] The selection of the starting dose depends heavily on pharmacology and toxicology from preclinical studies. Two measures useful in translating the drug potency in animals to that in humans are the dog toxic low dose (TLD), defined as the minimum dose at which any toxicity is observed, and the mouse lethal dose 10 (LD_{10}), defined as the dose that kills 1/10 of the animals. The starting dose in human trials is usually 10% of mouse LD_{10} if it was nontoxic in dog studies. If it was toxic in dogs, then 1/3 the dog TLD is often selected. Subsequent dose levels are often determined by a modified Fibonacci scheme. Let x_1 denote the starting dose. According to a

modified Fibonacci scheme, $x_2 = 2x_1$, $x_3 = 1.67x_2$, $x_4 = 1.5x_3$, $x_5 = 1.4x_4$, and thereafter, $x_{k+1} = 1.33x_k$.

The following two types of the traditional designs are popular. The traditional design without dose de-escalation is described as follows. Three patients are assigned at the first dose. We proceed to the next higher dose level with a cohort of three patients until at least one patient experiences the DLT. If at least two out of three patients experience the DLT, then the previous dose level is defined as the MTD. If one out of three patients experiences the DLT, then three more patients are treated at the same dose level. If at least one of the three additional patients experiences the DLT, then the previous dose will be considered as the MTD. Otherwise, the dose will be escalated.

The traditional design with dose de-escalation is the same as the above design except for the following things. If at least two out of six patients experience the DLT in the initial cohort and the additional cohort, or at least two out of three patients experience the DLT in the initial cohort treated at a dose level, then we have exceeded the MTD. We would treat another three patients at the previous dose level if there were only three patients treated at that level. Hence the dose may de-escalate until we either reach a dose level in which six patients are already treated or observe at most one DLT out of six patients. We define the MTD as the highest dose level (≥ 1) in which we have treated six patients with at most one patient experiencing the DLT or a dose level 0 if there were at least two patients experiencing the DLT at dose level 1. The level 0 is not a level at which we would treat patients. When the level 0 is decided as the MTD, in practice, dose levels are lowered and a new trial is conducted.

In most previous studies on phase I cancer clinical trials, a few scenarios of dose–toxicity relationships were selected and investigations were performed by simulation. Recently, Lin and Shih^[8] derived the exact formulae of key statistical properties of the traditional 3 + 3 designs both with and without dose de-escalation. Using their results, Kang and Ahn^[9,10] conducted the exact computation of several key statistical properties for hundreds of dose–toxicity curves that belong to the same family of increasing functions. The performance of the traditional designs depends on the unknown true dose–toxicity relationship and dose levels, which makes it hard to draw a general conclusion. However, investigations for the following logistic and the hyperbolic tangent functions shed some lights on the performance of the traditional designs.

$$\varphi_1(x_i : a) = \frac{\exp(1.5a + a \times x_i)}{1 + \exp(1.5a + a \times x_i)},$$

$$x_i = -4.0 + 0.5(i - 1), \quad 1 \leq i \leq 13$$

and

$$\varphi_2(x_i : b) = \left[\frac{\tanh(x_i) + 1}{2} \right]^b,$$

$$x_i = -1.4 + 0.25(i - 1), \quad 1 \leq i \leq 13$$

respectively. These two families of functions are plotted in Fig. 1. The exact computation of several key statistical properties is performed for each value of both $0.8 \leq a \leq 2.4$ for the logistic function and $0.5 \leq b \leq 2.0$ for the hyperbolic tangent function with the increment of 0.01. The expected toxicity rates at the MTD of the traditional designs without and with dose de-escalation are plotted for the logistic and the hyperbolic tangent functions in Fig. 2. The solid and dotted lines represent the traditional designs with and without dose de-, respectively. The expected toxicity rate at the MTD turns out to be between 17% and 22% for the logistic and the hyperbolic tangent dose–toxicity relationship if the toxicity rate is very small in low dose levels.^[10] The traditional designs are often considered to produce a 33% toxicity rate, but the authors are unaware of any published result to support this consideration. Fig. 3 displays the expected number of toxicity and the expected number of required patients in the logistic and the hyperbolic tangent functions. The solid and dotted lines represent the traditional designs without and with dose de-escalation, respectively. On average, five to six toxicities are expected to occur in the traditional design with dose de-escalation, while two to three toxicities are likely to occur in the design without dose de-escalation. The expected number of required patients ranges from 10 to 30, and the difference between the two designs is about three patients.

THE CONTINUAL REASSESSMENT METHOD

One problem with the standard design is that many patients are treated at low dose levels. Another problem is the large variability of the estimated MTD around the true MTD. The major criticism of the standard design is that it has no interpretation as an estimate of the dose level which yields a specified toxicity rate. The results of Kang and Ahn^[9,10] show clearly that it is difficult for the toxicity rate at the MTD determined from the traditional designs to be close to a given toxicity rate which is not between 17% and 22%.

O'Quigley et al.^[3] proposed the continual reassessment method (CRM), which reduces the number of patients treated with possibly ineffective dose levels. The starting dose of the CRM is selected to be the prior estimate of the MTD. When toxicity outcomes are known for successive patients, the dose–toxicity curve is updated and used to determine the dose at which to treat the next patient. Shen and O'Quigley^[11] established the consistency and asymptotic normality for the maximum likelihood estimates. They also showed that the recommended dose will generally converge to the target toxicity rate as the sample size increases. However, there are situations in which the recommended dose may converge to a level close to the target level, but not necessarily the closest. This contrasts with the conclusions of O'Quigley et al.^[3] Shen and O'Quigley^[11] describe this situation as well as provide the conditions under which convergence is assured.

The CRM is described as follows. Let $x_1, x_2, \dots, x_k$ denote the dose levels chosen for experiment. Let θ be the

probability of toxic response corresponding to the aimed target dose level. Let Y_i be a random variable for the response of the i th patient. The binary random variable Y_i takes on 1 for toxic response and 0 for nontoxic response. Consider some simple dose–response function for $E(Y_i)$ and denote this by $\Psi(x_i, a)$. Let $x(j)$ denote the dose level chosen for the j th patient. The CRM is performed as follows.

1. A mathematical model $\Psi(x_i, a)$ for dose–response is assumed. For example,

$$\Psi(x_i : a) = \frac{\exp(a_0 + a \times x_i)}{1 + \exp(a_0 + a \times x_i)},$$

$$\Psi(x_i : a) = \left[\frac{\tanh(x_i) + 1}{2} \right]^a$$

2. Assume a prior distribution for a , $g(a) = f(a, \Omega_1)$. For example, the exponential prior is popular.

$$g(a) = \exp(-a), \quad 0 < a < \infty$$

3. Define θ , aimed target toxicity level.
4. Assign the first patient in the dose level whose probability of toxicity is judged closest to θ .
5. After observing Y_j , the posterior distribution of a is modified. Specifically, let

$$\phi(x(j), y_j, a) = \Psi^{y_j}(x(j), a)(1 - \Psi(x(j), a))^{(1-y_j)}$$

Then, the likelihood of $(Y_1, \dots, Y_j, X_1, \dots, X_j)$ is

$$\prod_{l=1}^j \phi(x(l), y_l, a)$$

The updated posterior distribution of a after observing $(Y_1, \dots, Y_j, X_1, \dots, X_j)$ is

$$f(a, \Omega_{j+1}) = \frac{g(a) \prod_{l=1}^j \phi(x(l), y_l, a)}{\int_0^\infty g(u) \prod_{l=1}^j \phi(x(l), y_l, u) du}$$

where $\Omega_{j+1} = \{y_1, \dots, y_j\}$

6. We compute the posterior mean

$$\mu(j+1) = \int_0^\infty af(a, \Omega_{j+1}) da$$

Take $\hat{a} = \mu(j+1)$ and find the dose level for the next patient such that

$$\left(x_i - \Psi_{a=\mu(j+1)}^{-1}(\theta) \right)^2$$

is minimized.

7. We repeat steps 5 and 6 until we reach a predetermined fixed sample size, or some other trial terminating condition is satisfied. The recommended dose is the dose such that

$$\left(x_i - \Psi_{a=\mu(n+1)}^{-1}(\theta) \right)^2$$

is minimized.

The following example is from O'Quigley et al.^[3] Suppose that we use the following model

$$\Psi(x_i, a) = \left(\frac{\tanh(x_i) + 1}{2} \right)^a$$

and the exponential prior distribution.

$$g(a) = \exp(-a), \quad a > 0$$

Suppose that the true state is $a_0 = 0.5$ and the dose levels are given by

Dose level	1	2	3	4	5	6
x_i	-1.47	-1.1	-0.69	-0.42	0.0	0.42
$\Psi(x_i, a=0.5)$	0.22	0.32	0.45	0.54	0.69	0.80

Let the target toxicity rate be $\theta = 0.2$. Suppose that experimentation starts at $x(1) = x_3$. From Table 1 in O'Quigley et al.,^[3] we observe that $y_1 = 0$. Then

$$\begin{aligned} \phi(x(1), y_1, a) &= 1 - \left(\frac{\tanh(-0.69) + 1}{2} \right)^a \\ &= 1 - 0.201009^a \\ f(a, \Omega_2) &= \frac{\exp(-a)(1 - 0.201009^a)}{\int_0^\infty \exp(-u)(1 - 0.201009^u) du} \\ &= (1/0.616035) \exp(-a) (1 - 0.201009^a) \\ \mu_2 &= \int_0^\infty af(a, \Omega_2) da = 1.38 \end{aligned}$$

Solving $\Psi(x, \mu(2)) = 0.2$, we have $x = \theta - 0.3964$. Because x_4 is closest to x , x_4 is the next dose level. This is the way that $x(2) = x_4$ is found in Table 1.^[3]

Although the CRM outperforms the traditional designs, the original CRM has some difficulties to be implemented in real practice. One of them is that it takes too long to complete the trial because the CRM treats one patient at a time. Goodman et al.^[4] proposed the modified CRM that assigns more than one patient at a time to each dose level and limits the dose escalation by one level. Another modification is that the starting dose of the modified CRM is the lowest dose level, not the prior estimate of the MTD. This modification makes clinicians more comfortable, probably because treating at less effective doses is viewed less serious than treating at too toxic doses. Goodman et al.^[4] showed that the modified CRM reduces the duration of the trial by 50–67%, reduces a toxicity incidence by 20–35%, and lowers toxicity severity from the original CRM.

The modified CRM which leans to a Bayesian methodology can be changed to a classic framework leaning upon likelihood theory in which the maximum likelihood estimate is used instead of the posterior mean.^[12] Shen and O'Quigley^[11] proved the consistency and asymptotic normality for the maximum likelihood estimates under model misspecification. Cheung and Chappell^[13] interpreted the main condition under which the CRM is consistent and apply it to evaluate the model sensitivity in the CRM. With extensive simulation studies, Ahn^[6] compared nine phase I designs which include the traditional design, the two-stage modified Storer's design,^[14] the two-stage Korn's design,^[15] the modified CRM, and the two-stage modified CRM.^[5] In general, the modified CRM with two or three patients per cohort performs well compared with the other designs. Especially, the modified CRM has substantial gains in the chance of choosing the correct MTD than the traditional design.

Research on the CRM has been still active until a recent date. The CRM is modified to solve the problem of deciding the dose level of the next patient when toxicity cannot be observed immediately after treatment.^[16,17] Stopping rules based on a predetermined number of iterations^[2,4,18] and more sophisticated criteria have been studied.^[19–21] Another modification by O'Quigley et al.^[22] suggests the use of covariate information in CRM. Ishizuka and Ohashi^[23] proposed to monitor a posterior density function

of the occurrence of the DLT at each dose level instead of a which is difficult to interpret, especially for clinical investigators. Piantadosi and Liu^[24] and Legedza and Ibrahim^[25] proposed a method of incorporating pharmacokinetic data into a phase I cancer clinical trial which is a variant of the CRM. Braun^[26] extended the CRM to a bivariate trial design in which the MTD is estimated based on both toxicity and disease progression. The CRM employs a one-parameter dose–response curve such as the logistic or the hyperbolic tangent function. Gasparini and Eisele^[27] proposed a curve-free CRM in which the assumption of a specific dose–response is not needed, and Cheung^[28] modified the curve-free CRM when a low percentile of toxicity is targeted. However, O’Quigley^[29] pointed out that the curve-free method is equivalent to the usual model-based CRM.

OTHER DESIGNS

Storer^[14] proposed two two-stage designs (BC and BD), a combination of simple dose-escalation algorithms. In the first stage, a single patient is treated at each dose level. The next patient is treated at the next lower dose level if a toxic response is observed, otherwise at the next higher dose level. When the first toxicity is reached, the dose is decreased one level and the second stage begins with fixed sample size. In the second stage of the design BC, if none of two has DLT, then escalate, whereas if one or two of these have DLT, then de-escalate. In the second stage of design BD, three patients are treated in the second stage. Escalation occurs if no toxicity is observed, and de-escalation occurs if two or more patients have toxicity. If a single patient has toxicity, then the next group of three patients is treated at the same dose level. After completion of the second stage, a dose–response model is fitted to the data and the MTD is estimated by the maximum likelihood estimate.

Babb et al.^[30] proposed a Bayesian dose escalation with overdose control (EWOC) in which approaches the MTD as fast as possible subject to the constraint that the predicted proportion of patients who receive an overdose does not exceed a specified value. Instead of using a dose with toxicity deemed closest to the target toxicity at each update, as the CRM does, EWOC uses the dose with probability of higher toxicity than the current estimate of the MTD, not exceeding some critical value.

Leung and Wang^[31] proposed a new approach which requires no assumptions on the dose–toxicity relationship other than that the probability of toxicity is nondecreasing with dose. The method determines escalation and de-escalation after adjusting the toxicity estimates at each dose to ensure a nondecreasing order. The adjusted toxicity estimates are obtained from isotonic regression.

Durham et al.^[32] proposed random walk rules for phase I cancer clinical trials. It is simple to implement random walk rules, and finite and asymptotic distribution

theory is completely worked out. The small-sample properties of random walk rules determined by exact theory compare favorably to those of the CRM determined by simulation.

CONCLUSION

In summary, phase I clinical trials are challenged by reaching the MTD efficiently and quickly while offering patients safe and appropriate treatment. Thus an optimal phase I trial design must fully evaluate drug toxicity but, at the same time, must also minimize the likelihood of treating patients at both subtherapeutic and severely toxic doses. The traditional-cohort escalation trial design has many shortcomings because of small cohort sizes and its ad hoc nature. Recently, there has been increasing interests in reexamining the phase I trial design. To identify the MTD, methods have been proposed such as the CRM, Bayesian approaches, and up-and-down procedures or strategies for monitoring toxicity and efficacy. In the near future, we expect more publications of successfully conducted phase I cancer clinical trials that employed one of the designs described in this article.

LFB USA, Inc., Framingham, Massachusetts, U.S.A.

Abstract

Most of the drugs available in pharmacy started out as a chemical or biological compound discovered in laboratories. A chemical compound is relatively a smaller molecule synthesized in a laboratory, whereas a biological compound tends to be a large molecule extracted from living bodies, such as plant or animal tissues. When first discovered, this new compound is denoted as a product candidate. Medicinal product development is a process that begins when the product candidate is first discovered and continues until it is available to be prescribed by physicians to treat patients. It is usually a new chemical or biological entity synthesized by scientists from pharmaceutical companies, universities, or other research institutes. This new compound will have to undergo the product development process and obtain regulatory approval before it can be used by the general patient population.

Keywords: Phase II; Clinical development; Proof of Concept; dose-ranging; dose-response; go/no go decision.

BACKGROUND

Most of the drugs available in pharmacy started out as a chemical or biological compound discovered in laboratories. A chemical compound is relatively a smaller molecule synthesized in a laboratory, whereas a biological compound tends to be a large molecule extracted from living bodies, such as plant or animal tissues.^[1] When first discovered, this new compound is denoted as a product candidate. Medicinal product development is a process that begins when the product candidate is first discovered and continues until it is available to be prescribed by physicians to treat patients.^[2,3] It is usually a new chemical or biological entity synthesized by scientists from pharmaceutical companies, universities, or other research institutes. This new compound will have to undergo the product development process and obtain regulatory approval before it can be used by the general patient population.

The product development process can be broadly classified into two major components—non-clinical development and clinical development. Non-clinical development includes all product testing performed outside the human body, which can be further broadly divided into pharmacology, toxicology, and product formulation. In contrast, clinical development is based on studies conducted in the human body to understand how the human body reacts to the product candidate and, in addition, how the product candidate helps patients with the disease treatment or if it leads to any potential adverse events. Clinical development can be further divided into phases I, II, III, and IV.

Phase I trials are designed to study the short-term effects; e.g., pharmacokinetics (PK, what does a human body do to the drug?), pharmacodynamics (PD, what does a drug do to the human body?), and the upper bound of dose range [maximal tolerated dose (MTD)]. Phase II trials are designed to study the efficacy of the new product in well-defined patient populations, often with dose-response relationship as one of the major objectives. Phase III studies are usually longer term, large-scale studies to confirm findings established from earlier trials. These studies are also used to detect the adverse effects caused by cumulative dosing. If a new product is found to be safe and efficacious from the first three phases of clinical testing, in the United States, a New Drug Application for a new chemical entity or a Biological License Application for a new biological entity is submitted to Food and Drug Administration (FDA) for review. Once the new product is approved by FDA, phase IV (postmarketing) studies are planned and carried out. Many of the phase IV study designs are dictated by the FDA to examine safety questions; some designs are used to establish new uses or indications.

PHASE II CLINICAL DEVELOPMENT

Among all the phases of clinical development, phase II is one of the most important components^[4] before entering into the phase III trials. Phase III pivotal studies are typically large scale with very high cost (the cost in some of phase III studies could be even more than the total cost

spent from the very beginning of a compound discovery to the end of phase II studies). Therefore, a well-designed phase II study could be very beneficial to both patients and sponsors and accordingly reduce the time-to-market launch and/or increase the probability of success. Phase II is also the last opportunity to stop a bad (or not-so-good) candidate from moving further into phase III.

Phase II trials are designed to study the preliminary efficacy, explore a range of doses for phase III, and understand the safety profile of an investigational product. Unlike phase I studies (except for life-threatening diseases), subjects recruited in phase II studies are patients with the disease for which the product is developed. Response variables considered in phase II studies are mainly clinical efficacy variables and safety variables. For example, in a trial for the evaluation of hypertension (high blood pressure), efficacy variables are blood pressure measurements. For an anti-infective trial, response variables can be the proportion of subjects cured or the time-to-cure for each subject. Phase II studies are mostly designed with parallel treatment groups (in contrast to crossover designs). Hence, if a patient is randomized to receive dose A of the test product, then this patient is planned to be treated with dose A of this product throughout the entire study.

Phase II trials are often designed to compare one or a few doses of a test product against a placebo control. These studies are usually shorter term (e.g., several weeks) and designed with a small or moderate sample size. Patients recruited for phase II trials are somewhat restrictive, that is, they tend to be with a certain disease severity (e.g., moderate severity), without other underlying diseases, and are not on background treatments. The two major objectives of phase II clinical trials are to demonstrate preliminary clinical benefit, which is typically referred to as a proof of concept (PoC) study, and to explore a range of doses for phase III confirmatory trials, which is generally called phase IIb dose-ranging study.

A typical PoC trial includes two treatment groups—a placebo group and a testing dose group. The testing dose is typically the MTD or a dose that is slightly below the MTD. A dose-ranging trial usually includes multiple doses of the testing product and placebo. One typical dose-ranging trial uses placebo, low dose, medium dose, and high dose of the testing product. In general, PoC trials and dose-ranging trials tend to be parallel designs with fixed doses. Some phase II trials can have both the PoC part and the dose-ranging part built in to one trial. In this case, PoC part will be demonstrated first, followed by the dose–response explorations. From a dose-ranging point of view, the objective of phase I should be to help exploring the upper limit of dose range (MTD), and that of phase II should be to help finding the lower limit of targeted dose range. This lower limit is also known as minimum effective dose.

Design a Phase IIa PoC Trial

One of the natural questions in phase II stage is whether or not the investigational drug works for the target patient population. In most clinical development programs for treating chronic diseases, phase II is the first time the candidate product can be tested in patients with the target disease under study. It is generally the first time the product efficacy can be observed and evaluated. In other words, before the first phase II clinical trial, the sponsor does not have an opportunity to study whether or not the test product works in patients. Under this circumstance, it is especially important that the product efficacy be established from the first phase II clinical trial. The most commonly used study design for the first phase II clinical trial is a PoC study. A PoC typically includes two treatment groups—a placebo group and a test product treatment group. In order to offer the best opportunity for the test product to demonstrate its efficacy, the dose of test product used in a PoC should be the highest possible dose. And this dose is usually the MTD, or a dose that is slightly below MTD. This design allows the project team to make a “go/no go” decision on the test product after study results are obtained.

If the results fail to demonstrate a clear efficacy, then a “no go” decision can be made for this candidate product and further development can be stopped. The sponsor does not have to make more investment on it; budget and resources can be allocated to develop other candidates that show more promise for success. This approach can also be considered as a “sledgehammer” approach, because such a design helps simplify the conclusion to be a “make it or break it” result for the product under development; that is, a clear “go/no go” decision should be made based on the analysis of data obtained from the PoC study.

Another type of study is known as a “proof of mechanism” (PoM) study. In the laboratories in which basic research and discovery are performed, it is important that a good understanding of the “mechanism of action” be available for the compound that is being discovered. For example, before the beta blockers were developed for the treatment of high systolic blood pressure (SBP), the biological theory was that the beta receptors in heart muscles may increase SBP as a response to stress stimulants. Given this understanding, the laboratory scientists searched for a chemical structure that could bind to the beta receptors and inhibits their activities. Such a chemical compound could be considered as a “beta blocker” because it blocks the activities of beta receptors in heart muscles.

As discussed earlier, product efficacy cannot be established until phase II. However, in the case of developing a beta blocker, there could be opportunities to observe whether the mechanism of action can be demonstrated in a phase I clinical trial. This can be achieved by observing the activities of beta receptors in healthy normal

volunteers. In other words, although healthy subjects with normal SBP are recruited in phase I, activities of beta receptors from these subjects can still be measured. By assessing beta receptor activities from these subjects, a PoM objective could potentially be achieved. Oftentimes, the measurement that helps establishing PoM is denoted as a biomarker. Generally, PoM is not a well-defined, widely accepted term that applies to all candidate products. Only under certain situations where the marker can be easily identified, and clearly measured, a PoM study design would be contemplated.

Impact of PoC Decisions

Most PoC studies tend to have two treatment groups—one placebo control group and another treatment group, with a high dose of the candidate product. Some PoC studies are designed with more than two treatment groups. Generally, the PoC designs are based on two key assumptions: 1) the MTD estimated from phase I is appropriate; and 2) efficacy dose–response relationship is monotonic.

Under these two assumptions, the highest possible dose (either MTD or a dose slightly below MTD) of the test product offers the best opportunity to demonstrate efficacy response. In other words, if this dose does not show efficacy response, then there is no need to invest any more resources to develop this test product. Hence, only after the concept is proven, extended development activities can be funded and resources can be allocated to develop the compound under investigation.

A positive PoC result triggers many important development activities. A long-term toxicity study is one of those activities. Drug formulation and drug supply also depend upon a positive PoC. At early phase II, there is usually just enough drug supply to handle the first few dose-ranging studies. If the PoC result is positive, there will be more study medication needed for phase III clinical development and large amount of raw materials need to be ordered or manufactured. Moreover, depending on the dosage forms that may be necessary for additional phase II and phase III trials, various formulations of the candidate product will have to be prepared. On the other hand, if the concept is not proven, there is no need to stock up a huge pile of raw materials for the making of large quantities of the study drug or study biological compound.

Furthermore, additional bioavailability or bioequivalence (or both) studies may be necessary. In some situations, additional drug–drug interaction studies may also be needed. Therefore, a clear “go/no go” decision is critical from the PoC study results. When the study results are not clear (inconclusive), many of the important development activities will be delayed.

According to the clinical development plan for a study medication, if the phase III study needs to be of one-year duration, then (before the phase III study is started) a

one-year toxicity study on animals should be completed, with no safety findings. Usually such a one-year toxicity study will not be initiated unless the concept is proven from early phase II. In practice, if the “go/no go” decision is delayed because of inconclusiveness, then all these operations could be postponed and, eventually, this problem of inconclusiveness may delay the entire product development program.

How to Communicate Risks Associated with a PoC Study

Usually a statistician is involved in a study design when there is a need for sample size calculation. Sample size calculation is one of many essential contributions provided by a trial statistician. An experienced statistician will begin by understanding the primary end point and by probing its clinically meaningful difference, δ . Sometimes this quantity is readily available. However, in many cases, this could be the beginning of long discussions.

After the study completes, clinical data are analyzed and results are presented to the project team. The project team members and upper management evaluate these results and make a decision. A “go/no go” decision is easy if both statistical significance is observed and treatment difference exceeds δ , where δ is the postulated clinically meaningful difference. These results indicate a clear “go” decision. On the other hand, when the results are not statistically significant and the observed treatment difference is too small, then the team may make, oftentimes reluctantly, a “no go” decision. However, if the observed treatment difference is not too small, but failed to reach statistical significance, then the team is in a difficult position and not clear as to whether a “go” or a “no go” decision could be made with confidence. Under this circumstance, a situation of inconclusiveness prevails.

In many cases, when the observed p value is close to statistical significance, but not strictly statistically significant, the team tends to decide to move forward. However, further development could indicate this “go” decision was a mistake because the observed treatment difference was not large enough. These difficulties occurred because, at the time of designing PoC, a δ which is larger than the true desired treatment difference was used for various reasons. One typical case could be that such a δ was selected based on the available sample size; i.e., from the sample size and the given α and β , a treatment difference can be calculated. A larger δ was chosen so that such a PoC study was feasible under the given ethical concerns or budget constraints. However, after the PoC results are ready, although the observed treatment difference was actually smaller than the hypothesized δ , the project team may still make a “go” decision simply because the p value was either statistically significant or close to be significant.

On the other hand, there were situations where the decision was “no go” even when a statistical significance is observed, yet the clinically meaningful difference δ was not achieved. One example can be found when the PoC end point is different from the phase III end point. When this is the case, a lowest δ was selected for PoC and the decision rule was that, if the PoC results cannot deliver such a δ , then there is no hope for the test product to meet the phase III primary end point.

Under certain situations, the PoC study may have to be repeated so that a clear decision can be made. Inconclusiveness can be thought of, as the time period between the study results obtained and a definitive “go” or “no go” decision is made. During this period, the team could consider a “go” decision, even when the observed p is greater than α . On the other hand, if the observed p is less than α , but the observed treatment difference is less than δ , but a “no go” decision was made incorrectly (β could be inflated). In either case, the risk of making a wrong decision is greater than the prespecified error rate.

Based on the above discussion, it is clear that when there is an observed statistical significance, and the decision is “go”, then the risk of making a wrong decision is preserved under the prespecified level alpha (α). Also, when statistical significance is not observed, and the decision is “no go”, then the risk of making a wrong decision is also preserved under the prespecified level of beta (β). However, if a “go” decision is made when there is no statistical significance, then the risk of making a wrong “go” decision is increased to be more than the prespecified risk level (α). On the other end, when there is a statistical significance and a “no go” decision is made, then the risk of making a wrong “no go” decision is increased to be more than the prespecified β . Of course, these decisions are usually made after long discussions among team members after looking at all clinical data on hand—primary and secondary end points, multiple doses if more than one dose was used, safety data, sometimes PK or outcomes research data, and so on.

The main issue we hope to address in this entry is during the time between when the PoC data is ready and the actual decision is made, there is a period of time that the PoC study was considered as “inconclusive.” This time period is difficult because there is always tight timelines for the entire project—Will there be a need for a long-term toxicity study? When should it start? What amount of drug supply will be necessary? At what time frame (phase II requirements and phase III requirements)? What dosages are to be formulated? Will there be additional PK studies such as drug–drug interaction or food effect studies to be designed? At this time, a “go/no go” decision is very critical. Yet, the data are not always clear. Regardless of all these discussions and various perspectives, in the end, a decision has to be taken—to go or not to go. This problem becomes much more difficult when the PoC study needs to be repeated.

Although the design of a PoC study is considered as a “sledgehammer” approach, in practice, there could be many difficulties and challenges in decision-making after the study is completed. It is critical to consider that in the design stage of such a study, there should be sufficient discussions among team members with the objective of minimizing the risk of potential inconclusiveness.

Design a Phase IIb Dose-Ranging Trial

Once a PoC study is positive, the next question is “what is the appropriate range of doses that could deliver desired treatment benefit to patients with acceptable safety profiles?” A dose-ranging trial typically includes a placebo (representing zero dose) and several doses of the test product. One very common design is a four group study with placebo, low dose, medium dose, and high dose groups of the drug candidate under development. In practice, usually the first dose-ranging study covers a wide dose range, and then the next dose-ranging study will be designed with a narrower dose range and tease out the target doses to be assessed in phase III.^[5]

In general, the most difficult challenge in designing the first dose-ranging trial in clinical development of a new medicinal product is the selection of doses to be included in this design. Ideally, for the first dose-ranging study design, it is more important to cover a wide dose range, instead of simply adding more doses to a narrow range of doses. This is both practical and scientific. Basically speaking, a trial with four to five test doses, plus a placebo control will deliver a good understanding of where the test medication is most active, if the dose range is wide enough, and the dose spacing is reasonable.^[5]

The dose-ranging study is designed with two very important assumptions: 1) the MTD was correctly estimated from earlier trials; and 2) efficacy response is monotonic to ascending doses. However, it is unclear as to what is the range of doses and where the efficacy activities would be. At this stage, the best guidance available is data obtained from preclinical experiments or from phase I PK/PD studies. Even under the assumptions that the MTD was correctly estimated, and there is a monotonic efficacy dose–response relationship, there can be many possible shapes of dose–response curves.

It is common that a dose–response model is used in analyzing dose-ranging trials. Sometimes, the Multiple comparison procedures and modeling (MCP-Mod) is also applied to help making inferences from clinical trial data. However, from the study design point of view, use of a model could be based on additional assumptions. It is well-known that “All models are wrong, some are useful”. Designing dose-ranging trials based on a wrong model, or wrong parameters, could potentially lead to very undesirable consequences. In data analysis, after the blind is broken, efficacy dose–response data are observed. At this point, use of a model that “fits the data well” is a reasonable thing to do.

IMPORTANCE OF PHASE II CLINICAL DEVELOPMENT

An efficient development program is to progress a good candidate as fast as possible, so that patients will benefit from it at the earliest possible date. Meanwhile, the program should allow a bad candidate to be eliminated as early as possible so that the sponsor will not have to waste additional investments or resources on it.

Based on experiences accumulated, the best implementation of an efficient development strategy would be “design to stop.” In other words, design every study with a clear objective that if the candidate is not good enough, then stop developing it. With the concept of “design to stop” for every study design, it offers the opportunity to stop developing candidates with low likelihood of being successful at the earliest stage, saving investments and resources so that the entire development portfolio can be made more efficient. Under this strategy, a natural question would be, if every study follows the “design to stop” principle, how about those very good candidates? In fact, if a candidate is really good, it will demonstrate its strength given a reasonable decent robust design. Hence, a “design to stop” strategy tends to be one of the most efficient strategies of clinical development for new medicinal products.

One example of “design to stop” is that in most of the development programs, the first phase II clinical trial is a PoC trial. Such a design allows the candidate the best opportunity, if a non-decreasing dose–response trend holds, to demonstrate its efficacy by using the highest allowable dose and to compare it with an agent known to be ineffective (placebo). If under this setting, the candidate still cannot show efficacy, the sponsor would be comfortable to stop developing it. This paradigm is a common example of the thinking behind “design to stop.” In other words, this strategy allows an unsuccessful candidate to be eliminated at the earliest stage.

In contrast to “design to stop,” another strategy would be “design to progress.” If the sponsor has much confidence on the candidate being developed, and decided to design a PoC study with an active control, to allow the experimental candidate to be compared with an active control intervention that is already approved for the indication being studied; the active agent could be a standard intervention and one of the market leaders. If the candidate is really strong, it could be superior to the active comparator, and the sponsor would then progress this candidate aggressively. The downside of such a design is that if the candidate is non-superior to the active control, then it is not known whether the candidate works in some way. Given this example, it helps to clarify what is meant by “design to progress,” which is a contrast strategy to “design to stop.” Statistically, the idea of “design to stop” is implemented by a clear primary statistical hypothesis in comparing against placebo with a strict control on the level of significance (α).

The two major types of phase II clinical trials are PoC studies and dose-ranging studies. A dose-ranging study can be thought of both as a confirmatory study and as an exploratory study. It can include statistical hypotheses with multiple comparison adjustments to ensure α protection. It can also include modeling or estimating dose–response relationship, where responses at a given dose or within a range of doses could be obtained.

One of the most important objectives of the phase II clinical development program is to help propose particular doses or a range of doses to help with the designs in the pivotal phase III trials. It is important to note that in product approval, for a given dose of the study product, if it is safe and efficacious at that dose, then that dose can be approvable. Hence, after the product is approved and prescribed for the general patient population, it will be very difficult to study a dose of this product which is lower than the doses studied in phase II or higher than a dose that is evaluated at phase III. In other words, phase II is the critical time of exploring a wide range of doses. If this dose range is not studied in phase II, then the opportunity of learning dose–response relationship for that range of doses is lost.

For a product candidate to enter phase III clinical development, it is a huge sponsor commitment to move the candidate forward. A typical phase III program includes much larger scale, longer term clinical trials that require tens or hundreds of million dollars of investments. In the United States, the FDA encourages sponsor to set an “end of phase II” meeting with FDA. End of phase II and beginning of phase III are very critical from a sponsor’s point of view. Because this is the last milestone point for a sponsor to stop developing a product that may not be deemed “successful” (here, successful is considered as both a regulatory success and a commercial success; i.e., the product can be approved and marketed so that development investments can be returned). Note that a product that is not very successful is different from a failed product. A sponsor needs to evaluate the likelihood of a candidate being successful in terms of the huge amount of investments for the entire development program. There are many examples where a candidate failed after phase III—it did not receive any approval even when some of the phase III trial results were beneficial and noteworthy. There are also many examples where products were successfully approved by regulatory agencies but failed to generate meaningful returns of investments. Therefore, for any given candidate at the stage between late phase II and early phase III, the sponsor needs to evaluate all evidence obtained from non-clinical and phase I and phase II clinical studies to project how likely this candidate can be eventually successful. Based on these critical thinking and benefit/risk evaluations, a sponsor makes the very important “go/no go” decision on the candidate being developed to determine whether the candidate can be progressed to phase III.

Given the fact that phase II is the stage where a product candidate first demonstrates its activity in patients with the disease, and helps a sponsor in making the “go/no go” decision of progressing the candidate to phase III, phase II can be thought to be the most important phase across the entire product development process.

Phase III Clinical Trials with Response-Adaptive Allocation

Atanu Biswas

Indian Statistical Institute, Kolkata, India

Rahul Bhattacharyya

University of Calcutta, Kolkata, India

Abstract

Response-adaptive allocation, usually considered in a phase III clinical trial, is advocated to satisfy the ethical requirement of skewing the allocation in favor of the better treatment arm. We discuss the logistics and models of the designs in two frameworks—one using response and allocation history and the other where the allocation probabilities are estimated functions of parameters of response distributions. We then discuss several important issues like covariate, longitudinal, and multivariate data; Bayesian designs; and real-life applications of response-adaptive designs.

Keywords: Delayed response; Drop-the-loser; Link function-based allocation; Longitudinal response; Optimal target; Play-the-winner; Randomized play-the-winner; Sequential maximum likelihood estimates; Skewing allocation; Urn model.

INTRODUCTION

Response-adaptive allocation, usually considered in a phase III clinical trial, is advocated to satisfy the ethical requirement of skewing the allocation in favor of the better treatment arm. We discuss the logistics and models of the designs in two frameworks—one using response and allocation history and the other where the allocation probabilities are the estimated functions of parameters of response distributions. We further discuss several important issues like covariate, longitudinal, and multivariate data; Bayesian designs; sample size calculations; and real-life applications of response-adaptive designs.

WHAT IS RESPONSE-ADAPTIVE ALLOCATION?

Clinical trials are the scientific experiments involving human beings to evaluate the performance of the new drugs or therapies (referred to as treatments) over the existing. Evaluation of new treatments requires recruitment and allocation of subjects to the treatments under consideration. But, prior to the actual experiment, the clinician is at the state of *equipose* and tends to assign equal number of subjects to each treatment arm for possible evaluation of the treatments. Again, among the treatments under consideration, there is superior as well as inferior treatments and allocation without considering the treatment effectiveness outweighs the ethical imperative of providing the best possible care for individual patients within the trial. A clinical trial usually takes months or years to recruit

the patients. However, if the responses are immediate or reasonably quick to obtain, the clinician can repeatedly evaluate the performance of the treatments based on the currently available information, i.e., response, allocation, and covariate history of the already-assigned patients together with the current patient's covariate information for the allocation of the next incoming patient. Treatment allocation procedures for the incoming subjects based on the accrued information so far are known as *adaptive allocation designs* or simply *adaptive designs*. Depending on the nature of the information used for adjustment, treatment allocation procedures are either treatment-adaptive (if only treatment allocation information is used for adjustment) or response-adaptive (if allocation and response information is used for adjustment). In a response-adaptive allocation, coupled with the current patient's covariate information, the available covariate information is used, and thus the allocation is referred to as covariate-adjusted response-adaptive (CARA).

Thus, the key element of any response-adaptive allocation is the sequentially adjusted allocation probabilities. A non-trivial (i.e., other than 0 and 1) allocation probability ensures concealment of the allocation and hence reduces selection bias, but trivial extreme allocation probabilities make the allocation deterministic.

However, the usefulness of a response-adaptive allocation can be best explained if we consider redesigning a real data set. Consider a data set comparing azidothymidine (AZT) and placebo to reduce maternal to infant HIV transmission.^[1] In the trial, following an equal allocation procedure, out of a total of 476 patients, 238 pregnant

women were assigned to each treatment arm. A total of 60 newborns were found to be HIV positive in the placebo group and only 20 were found to be HIV positive in the AZT group. Zelen and Wei^[1] illustrated that a randomized play-the-winner (PW) rule (a response-adaptive design, to be described later on) could allocate in a 300:176 ratio with a standard deviation (SD) 20. In Table 1, we provide an illustration of such different response-adaptive designs for binary responses with the aid of this data set to give an indication of the benefits out of different standard designs, where we present the expected allocation ratio, its SD, and the expected number of failures for different allocation designs. These illustrate the benefits from response-adaptive designs.

Similarly, we consider the data set from a trial of fluoxetine hydrochloride.^[2] The response is the negative of reduction in the HAM-D¹⁷ score, which is in the 52-point scale. In the trial, the patients were classified according to the rapid eye movement latency (REML) status. However, we consider only the patients with shortened REML (42 in total) for our purpose and, treating the responses to be continuous, we calculate the final mean scores, which are 10.67 (with SD = 5.50) for fluoxetine and 5.53 (with SD = 7.75) for placebo. Treating these as the true parameter values of the response distributions, we redesigned the trial using different response-adaptive designs for continuous responses. The expected allocation ratio together with its SD, and the expected total responses are provided in Table 1, along with some other response-adaptive designs (described later on) to illustrate the promise of response-adaptive designs. The figures of Table 2 tell the same story of assigning more patients to the better treatment.

Table 1 Redesigning AZT trial using response-adaptive designs

Design	Expected allocation ratio	SD	Expected/actual number of failures
Observed	238:238	—	80
PW	356:122	21	60
RPW	328:148	53	65
DL	357:119	19	64
RSIHR	249:127	11	78

Table 2 Redesigning fluoxetine trial using response-adaptive designs

Design	Expected allocation ratio	SD	Total expected/actual responses
Observed	21:21	—	356
BB	30:12	5	400
N-BB	30:12	5	400
CDL (c = 0)	25:17	3	370
BM (c = 0)	28:14	5	391

RESPONSE AND ALLOCATION HISTORY-BASED ALLOCATIONS

Binary Responses

Play-the-Winner (PW) Allocation

Consider a clinical trial involving two treatments (say treatments 1 and 2) and assume that the responses are binary (i.e., of success/failure type) and immediate. The first significant contribution on sequential designing a trial in a response-adaptive manner is the PW rule of Zelen.^[3] A PW allocation assigns an incoming subject based on the outcome of the previous patient's response; if the previous patient's response is a success, the same treatment is assigned to the next patient, but other treatment is assigned for a failure. For example, if the previous patient was assigned to treatment 1 and a failure is observed, PW assigns the next subject to the opposite treatment (i.e., treatment 2) with probability one.

Randomized PW (RPW) Allocation

For the PW procedure, given the allocation-and-response history of the previous patients, the allocation probabilities are either 0 or 1, and hence there is selection bias. Wei and Durham^[4] incorporated treatment unpredictability in the PW allocation using all available response and allocation information from all the previously allocated patients. The allocation procedure is described by an urn model with two types of balls representing two treatments. Initially, the urn contains α balls of each type. For the allocation of an incoming subject, a ball is drawn with replacement and the corresponding treatment is assigned. If the patient's response is a success, additional β balls of the same type are added to the urn; and if the patient's response is a failure, β balls of the opposite type are added. The rationale behind the allocation is to enhance the chance of assigning the treatment *doing better*. The resulting allocation is known as the randomized PW or RPW (α, β) rule. For example, in an RPW(2,1) rule, the first patient is assigned to either of the treatments with equal probability. Suppose that the first patient is assigned to treatment 1 and a success is observed. Then, a treatment 1 type ball is added to the urn keeping treatment 2 type balls unchanged at two. Thus, the urn now contains a total of $(4 + 1) = 5$ balls, and hence the chance of selecting a treatment 1 type ball is $\frac{2+1}{5} = \frac{3}{5}$, which is nothing but the assignment probability of the second subject to treatment 1. However, the assignment probability for the second subject to treatment 1 would be $\frac{2}{5}$, if a failure is observed for the first patient.

However, the number of treatments under consideration may be more than two and the corresponding extensions with mathematical details can be found in further works.^[5,6] The RPW rule is a particular case of the Generalized

Friedman's Urn.^[5] Also, *delayed response* for the RPW rule has been studied by Bandyopadhyay and Biswas.^[7]

Birth and Death Urns

If an extra ball is added to the urn for a success and nothing is done for a failure, we get randomized Pólya urn^[8] (RPU). On the other hand, if a ball is added for a success and removed for a failure, a birth and death process can be generated. However, removal of balls enhances the chance of exhausting balls of a treatment type and hence the concept of immigration balls are introduced. Specifically, apart from treatment type balls, the urn contains immigration balls with number equal to the number of treatments. If an immigration type ball is drawn, no patient is allocated, and the immigration ball is replaced together with additional balls, one ball of each treatment type. The procedure is repeated until a treatment type ball is drawn. Again, if we allow to remove a ball for failure, do nothing following a success and introduce immigration balls, we get drop-the-loser (DL) allocation.^[9] Embedding these designs into a continuous time stochastic process, different properties are investigated.

If N_{kn} assignments to treatment $k = 1, 2$ are observed out of a total of n assignments in a clinical trial, the observed allocation proportion $\frac{N_{kn}}{n}$ to treatment k is an indicative measure of the ethical capacity of the allocation. Assuming $p_k (= 1 - q_k)$ as the success probability for treatment k , we provide the long run value of $\frac{N_{kn}}{n}$ for different allocation designs in Table 3.

It is easily observed that these ratios exceed $\frac{1}{2}$, if treatment 1 is better than treatment 2 and vary from $\frac{1}{2}$ according to the degree of superiority of treatment 1 (except for RPU). Interestingly, the limiting allocation proportions for PW, RPW, and DL rules are the same and are proportional to $\frac{1}{q_i}$; however, their small sample performances differ. Thus, more allocation is expected in the long run if the treatment has the least failure rate.

Categorical Responses

Often the responses in a clinical trial are measured in an ordinal categorical scale like nil, mild, moderate, severe,

etc. Clubbing the categories, one can transform the data to binary and can run the urn-based procedures for allocation. But, clubbing the categories results in loss of information and hence allocation designs for categorical responses are more sensible. Bandyopadhyay and Biswas^[6] upgraded the two treatment RPW considering $\ell + 1$ ordered categories $0, 1, \dots, \ell$ for responses. The allocation starts with an urn containing α balls of each type. If treatment k is assigned and the response is j , an additional $j\beta$ balls of type k along with $(\ell - j)\beta$ balls of the opposite kind are added to the urn. A subsequent update within the framework of DL rule with high skewing ability and less variability is also available.^[14]

Continuous Responses

The urn model-based allocations require binary treatment responses, but the responses may be continuous in practice. Ivanova, Biswas, and Lurie^[10] developed a continuous version of the DL rule (referred to as CDL) considering discretization, which was further modified^[11] by introducing the idea of fractional balls to reduce variability of the observed allocation proportion. Another urn design for continuous responses can be found in the work of Bandyopadhyay and Biswas^[12] (referred to as N-BB, N stands for non-parametric), where a Wilcoxon–Mann–Whitney-type statistic is used to update the urn. They obtained the limiting allocation proportion to treatment 1 as $P(X_1 > X_2)$, where the continuous response variable for treatment k is denoted by X_k .

ESTIMATED PARAMETER-BASED ALLOCATION USING LINK FUNCTIONS

The central idea behind an estimation-based allocation is the specification of a target allocation function. Suppose we have t treatments and the response distribution to treatment k involves the parameter θ_k . Then a target allocation function for treatment k is a function $\rho_k(\theta_1, \dots, \theta_t) \in [0, 1]$ such that:

$$\sum_{k=1}^t \rho_k(\theta_1, \dots, \theta_t) = 1 \quad (1)$$

for all $\theta_k, k = 1, \dots, t$. The choice of ρ_k is motivated by either ethical issue or precision or a convenient combination of both.

Link Function–Based Design for Continuous Responses

For continuous responses, the idea of link function-based allocation was developed through *treatment effect mapping*^[13] in a non-parametric setup. For two treatment trials, the idea is to assign the $(i + 1)$ st incoming subject to

Table 3 Limiting allocation proportion (LAP) to treatment 1

Design	LAP to treatment 1
Equal	$\frac{1}{2}$
RPU	$I(p_1 > p_2)$
BDU/BDUI	$\frac{\frac{1}{p_1 - q_1}}{\sum_{i=1}^2 \frac{1}{p_i - q_i}}$ if $\frac{1}{2} > p_1 > p_2$
PW/RPW/DL	$\frac{\frac{1}{q_1}}{\sum_{i=1}^2 \frac{1}{q_i}}$

treatment 1 with probability $g(\hat{\Delta}_i)$, where $\hat{\Delta}_i$ is the available estimate of some treatment effect measure Δ and $g(\cdot)$ is a function on $[0,1]$ ensuring ethical norms. Rosenberger^[13] continued the development with $g(x) = \frac{1+x}{2}$ and $\hat{\Delta}_i$ as the available estimate of the centered and scaled linear rank statistic. For survival outcomes, when some observations are subject to censoring, Rosenberger and Seshaiyer^[14] developed a response-adaptive allocation considering g as above but with $\hat{\Delta}_i$ as the centered and scaled log-rank test statistic.

An important link function-based allocation can be found in Bandyopadhyay and Biswas^[15] (referred to as BB), where an allocation is developed for normal linear model-based responses. In particular, if the response distribution of treatment k is $N(\mu_k, \sigma_k^2)$, the allocation probability for the $(i+1)^{\text{st}}$ patient to treatment 1 is given by $G(\hat{\mu}_{1i} - \hat{\mu}_{2i})$, where $\hat{\mu}_{ki}$ is the estimate of μ_k based on the data from the first i patients, and $G(\cdot)$ is the cumulative distribution function (cdf) of a random variable which is symmetric about 0. Bandyopadhyay and Biswas^[15] suggested to take:

$$G(\hat{\mu}_{1i} - \hat{\mu}_{2i}) = \Phi\left(\frac{\hat{\mu}_{1i} - \hat{\mu}_{2i}}{T}\right) \quad (2)$$

for some tuning parameter $T (> 0)$, reflecting the information on response variability. In fact, one can take $T = \sqrt{\hat{\sigma}_{1i}^2 + \hat{\sigma}_{2i}^2}$ in case of unequal variances. This design is based on ethics; the allocation probability is 50% for no (estimated) treatment difference and gets skewed in favor of the treatment producing higher observed mean response (i.e., the treatment doing better) at any stage. Suppose, at any stage, the estimates of the parameters based on the available data so far are $\hat{\mu}_1 = 10.67$, $\hat{\mu}_2 = 5.53$, $\hat{\sigma}_1 = 5.50$, and $\hat{\sigma}_2 = 7.75$. Then, the probability of allocating the next patient to treatment 1 is:

$$\Phi\left(\frac{10.67 - 5.53}{\sqrt{5.50^2 + 7.75^2}}\right) = 0.7057 \quad (3)$$

In fact, this will be the allocation probability to treatment 1 for the 43rd patient in the shortened REML group.

Ethics-Based Target Allocation Functions

Ethics is the main driving force in assigning a larger fraction of subjects to the better treatment. Thus, if we maintain a higher allocation probability to the better treatment, ethical requirements are fulfilled. In particular, assume that the unknown parameters θ_k , $k = 1, \dots, t$, are related to the location of the response distributions and higher responses are desirable. Then, increasing values of θ_k indicate the increasing superiority of the k^{th} treatment and the inequality $\theta_k > \theta_s$ signifies the superiority of treatment k over treatment s . Ideally, an ethics-based target $\rho_k(\theta_1, \dots, \theta_t)$ must be increasing in θ_k for fixed θ_s , $s(\neq k) = 1, \dots, t$. Moreover, the ordering $\theta_k > \theta_s$ must imply

the corresponding ordering of target allocation functions, that is, $\rho_k(\theta_1, \dots, \theta_t) > \rho_s(\theta_1, \dots, \theta_t)$.

For example, consider binary responses with success rate θ_k for treatment k , and the odds ratio-based target:^[16]

$$\rho_k(\theta_1, \dots, \theta_t) = \frac{\frac{\theta_k}{1-\theta_k}}{\sum_{j=1}^t \frac{\theta_j}{1-\theta_j}}, k = 1, \dots, t \quad (4)$$

Then, under the equality of success rates, $\rho_k = \frac{1}{t}$ for all $k = 1, \dots, t$, and ρ_k satisfies the other desirable properties.

If a higher response is desirable, treatment k is regarded as the *most promising* if it is capable of producing larger responses more frequently than its competitors or equivalent, if X_k is stochastically larger than any X_s ($s \neq k$). Thus, the relative effectiveness measure $P(X_k > \max_{s \neq k} X_s)$ can be taken as the target allocation function ρ_k for treatment k to provide a unique target allocation function using the knowledge of the response distributions.^[17] However, if the response for the k^{th} treatment is normal with mean θ_k and variance σ_k^2 in a two treatment trial, target allocation for treatment 1 reduces to:

$$\rho_1 = P(X_1 > X_2) = \Phi\left(\frac{\mu_1 - \mu_2}{\sqrt{\sigma_1^2 + \sigma_2^2}}\right) \quad (5)$$

as the same target function developed in Eq. 2.

Target Allocation Functions Combining Ethics and Precision Measures

Ethics and precision usually act in the opposite directions and for a meaningful combination, we primarily need relevant measures of ethics and precision. Assume that n_{kv} subjects are assigned to treatment k ($= 1, \dots, t$). Then, an ethical metric can be expressed as $G_E(n_1, \dots, n_t) = n_1 \Psi_1 + \dots + n_t \Psi_t$, where Ψ_k measures the ethical capacity of treatment k . For example, in binary response trials, $\Psi_k = 1 - \theta_k$ results in $G_E(n_1, \dots, n_t)$ as the total number of failures. Again, in a continuous response trial, if a lower response is favorable, the clinician might want to minimize the total expected responses.

$$G_E(n_1, \dots, n_t) = \sum_{k=1}^t E(X_k) \quad (6)$$

On the other hand, for a measure of precision $G_V(n_1, \dots, n_t)$, one can take some suitable functions of the Fisher's information matrix like $|I^{-1}(\theta | n_1, \dots, n_t)|$ or $\text{Trace}(I^{-1}(\theta | n_1, \dots, n_t))$. Thus, the optimum proportion $\frac{n_k}{n_1 + \dots + n_t}$, $k = 1, \dots, t$, compromising the ethical and the statistical needs, could be derived from the following constrained optimization problem:

$$\text{Minimize } G_E(n_1, \dots, n_t) \quad (7)$$

subject to the restriction:

$$G_v(n_1, \dots, n_t) \leq \kappa \quad (8)$$

where κ is a constant. Depending on the situation, there may be more than one restrictions. Equivalently,^[18] the optimum proportions can be derived by minimizing weighted objective function $wG_E(n_1, \dots, n_t) + (1-w)G_v(n_1, \dots, n_t)$ for $w \in (0,1)$. However, often we are interested in some linear combinations $A^T\theta$ of the parameters. For example, in binary response trials, the parametric functions of interest are often the differences $\theta_i - \theta_t, i=1, \dots, t-1$ with treatment t as the “control” treatment. In such a situation, it is natural to take $G_v(n_1, \dots, n_t)$ as some function of $A^T\Gamma^{-1}(\theta|n_1, \dots, n_t)A$. Considering the above choice, Atkinson and Biswas^[19,20] suggested another way to combine ethics and optimality to develop response-adaptive D_A -optimal designs. However, the problem becomes complicated when multiple treatments are involved. However, an alternative formulation^[21] considers the non-centrality parameter of the large sample contrast test of homogeneity for testing $H_0: \theta_1 - \theta_t = \theta_2 - \theta_t = \dots = \theta_{t-1} - \theta_t = 0$ as a precision measure. Since the power function of such a test is increasing in the non-centrality parameter $\phi(n_1, \dots, n_t)$, it is suggested^[27] to take the constraints $\phi(n_1, \dots, n_t) \geq \kappa$ and $\frac{n_j}{\sum_{k=1}^t n_k} \geq B, j=1, \dots, t$, where $\kappa (>0)$ is a constant and $B \in [0, t^{-1}]$ instead of $G_v(n_1, \dots, n_t) \leq \kappa$.

As examples, consider a two treatment binary response trial with success probability θ_k for treatment k . If we take $\psi_k = 1 - \theta_k$ and $G_v(n_1, n_2) = \text{Trace}(\Gamma^{-1}(\theta|n_1, n_2)) = \frac{\theta_1(1-\theta_1)}{n_1} + \frac{\theta_2(1-\theta_2)}{n_2}$, then the optimal proportion to treatment k is the well-known RSIHR^[22] target:

$$\rho_k = \left(\frac{n_k}{n_1 + n_2} \right)_{\text{opt}} = \frac{\sqrt{\theta_k}}{\sqrt{\theta_1} + \sqrt{\theta_2}}, \quad k=1,2 \quad (9)$$

However, these authors interpreted $G_v(n_1, n_2)$ as the variance of the estimated treatment difference.

Our next example is based on continuous responses, where we assume that a lower response is desirable. Then any response exceeding a clinically significant threshold c could be defined as a failure and hence $G_E(n_1, n_2)$ with $\psi_k = P(X_k > c)$ could measure the total number of failures for continuous response trials. Considering the variance of the estimated treatment difference or equivalently the trace of the inverse of the information matrix as the measure of precision, we can get the optimal allocation function of Biswas and Mandal^[23] (referred to as BM).

Implementing the Target Allocation Function

The target allocation functions, discussed so far, involve unknown parameters and hence cannot be applied straight a way in practice. For practical implementation, a doubly

adaptive biased coin design^[24,25] (DBCD) can be used. For two treatments, if the prefixed allocation function to treatment 1 is ρ_1 , then the allocation probability of the $(j+1)^{\text{st}}$ subject to treatment 1 is $g^{(\gamma)}\left(\frac{n_{1j}}{j}, \hat{\rho}_{1j}\right)$ with $g^{(\gamma)}(x, \rho_1) \in [0,1]$, defined by:

$$g^{(\gamma)}(x, \rho_1) = \begin{cases} 1 & \text{if } x = 0 \\ \frac{\rho_1 \left(\frac{\rho_1}{x}\right)^\gamma}{\rho_1 \left(\frac{\rho_1}{x}\right)^\gamma + (1-\rho_1) \left(\frac{1-\rho_1}{1-x}\right)^\gamma} & \text{if } 0 < x < 1 \\ 0 & \text{if } x = 1 \end{cases} \quad (10)$$

where $\gamma (\geq 0)$ is a randomness controlling parameter. Under certain restrictions^[25] on g , DBCD achieves the desired target ρ_1 in the long run. For $\gamma = 0$, DBCD reduces to the Sequential Maximum Likelihood Procedure^[22], where $g^{(\gamma)}(x, \rho_1) = \rho_1$, and at each stage maximum likelihood estimates of the unknown parameters are plugged in the expression of ρ_1 . The subsequent extension to accommodate multiple treatments is also developed.^[21]

DIFFERENT ISSUES

Covariates

Covariates are the auxiliary information associated with the study subjects, influencing their responses. For an enumeration of the importance of covariates, we consider the results from the Stroke Prevention in Atrial Fibrillation (SPAF) trial.^[26] The randomized trial compares two treatments, namely, *aspirin* and *placebo*, in the presence of a single binary covariate. The covariate is an indicator of the anticoagulation status (whether receiving or not). SPAF trial resulted in a significant difference between *aspirin* and *placebo* in reducing the number of strokes among patients receiving anticoagulation. However, no worthwhile difference was observed among the patients without receiving the anticoagulation therapy and this illustrates that the treatments perform differently for patients with different covariate profile. As a result, if we ignore the interaction between the treatments and the covariate, *aspirin* would be prescribed for every patient to reduce stroke. Therefore, the randomization probability of an incoming subject must include the covariate information, apart from the other available information.

One of the attempts can be found in the study by Bandyopadhyay and Biswas,^[27] where the RPW allocation is modified to incorporate categorical covariate information. Like the original RPW allocation, the modified version rewards the successful treatment with the addition of more balls but the number depends on the covariate category of the patient. In particular, following a success, for a patient with unfavorable covariate category, they allowed addition of more balls of the same kind and less

balls of opposite kind. However, for the same response with a favorable covariate category, number of balls to be added is lower than that for the unfavorable covariate category. Assuming the same, a covariate-adjusted DL allocation is also developed^[28] and studied in detail. For linear model-based responses, one can use the covariate-adjusted estimates $\hat{\mu}_{1i} - \hat{\mu}_{2i}$ to develop a covariate adjusted version of Eq. 2. A CARA design for a general class of continuous responses can be found in the study by Biswas and Bhattacharya.^[29]

Longitudinal Responses

Quite often, the patients in a clinical trial are monitored over a period of time and repeated responses (i.e., longitudinal responses) are obtained. For example, after treatment, the patient may be examined twice a week over a period of two weeks for the assessment of disease status, which gives a sequence of upto four correlated responses. For such responses, Biswas and Coad,^[30] Biswas and Dewanji^[31,32] extended the popular RPW allocation considering two treatments and longitudinal binary responses. Like the RPW (α, β) procedure, the allocation for longitudinal responses starts with an urn containing α balls of two types. If, at some monitoring time, recurrence (i.e., failure) is observed for a patient, β balls of the opposite treatment type are added to the urn whereas for a non-recurrence (i.e., success), β balls of the same type are added. As an example, consider the allocation of the third incoming patient. If the first patient is assigned to treatment 1 and has two successes and one failure so far, and the second patient has one failure so far on treatment 2, then the urn contains $\alpha + 3\beta$ balls of type 1, and $\alpha + \beta$ balls of type 2. Thus, the allocation probability to treatment 1 for the third patient is simply $\frac{\alpha+3\beta}{2\alpha+4\beta}$. However, the first two patients will give more responses subsequently and the urn will be updated accordingly each time. For further development in the presence of covariate information' refer the study by Biswas, Bhattacharya, and Park.^[33]

Multivariate Responses

Responses obtained from the treated subjects can be multivariate in nature. Quite often, safety and efficacy are the two components of a bivariate response. Development of a response-adaptive allocation in such cases requires the utilization of the multivariate response history for any assignment. Biswas and Coad^[30] generalized the link function-based design (Eq. 2) considering multivariate responses and multiple treatment situations.

Missing Data

Possibility of missing responses is a rarely addressed issue in the context of response-adaptive designs. One exception

can be found in the study by Biswas and Rao,^[34] where an allocation design is developed for the normal linear model-based responses assuming missing-at-random responses and complete availability of the covariate information. Specifically, they suggest to impute the missing responses at each stage and considering the available (i.e., observed and imputed) response and covariates; estimates of the treatment difference are calculated and plugged into Eq. 2 to get the allocation probability of the next incoming subject.

Bayesian Designs

Response-adaptive designs are data-driven, and hence it has similarity with the Bayesian philosophy of prior utilization. One of the response-adaptive designs developed in a Bayesian paradigm can be found in the study by Biswas and Angers,^[35] where the allocation probability at each stage is the predictive density of the allocation indicator of the incoming patient. Assuming two treatments and normal linear model-based responses, they developed an allocation function considering covariates.

Real-Life Applications

Real-life applications of response-adaptive designs are very limited. The initial RPW allocation-based Michigan extracorporeal membrane oxygenation (ECMO) trial^[36] was a disaster mostly due to the small sample size and inefficient choice of design parameter. The Boston ECMO trial^[37] was another application of RPW rule, whereas crystalloid preload trial^[38] was an application of PW rule. Eli Lilly sponsored Fluoxetine trial^[2] was again an RPW-based application. Biswas and Dewanji^[31,32] illustrated a real clinical trial with rheumatoid arthritis patients for longitudinal responses. However, the authors feel that more coordination between the practitioners and the academicians is needed in order to have more and more successful response-adaptive allocations in practice.

Power and Variability

Response-adaptive allocations usually favors the better performing treatment arm for further allocation. But such an allocation induces correlation among the treatment assignments and causes, in general, a loss in statistical power. However, under fairly general conditions and large sample sizes, it can be established that loss in power is inversely proportional to the variability of the observed treatment assignments.^[39] Therefore, among a number of response-adaptive designs targeting the same allocation proportion, the design with the minimum variability seems best. A class of such allocations, referred to as *asymptotically best*, can be found depending on the attainment of the

lower bound on the asymptotic variance of the observed allocation proportion.^[40]

Sample Size Calculation

The primary objective in most of the clinical trials is to explore the safety and effectiveness of the treatments under study. Then it is natural to have sufficient number of patients in the study to establish the effects of the treatments with certain statistical precision. Therefore, sample size calculation at the planning stage is necessary to ensure detection of a clinically significant difference with high probability. Usually sample size calculation depends on the specification of a significance level (say, α), power of a relevant test (say, $1 - \beta$), and a clinically significant difference (say, Δ). As a simple example, assume that the response variable (may be continuous, binary or time-to-event) for treatment k has unknown mean μ_k and known variance $\sigma_k^2, k = 1, 2$. For specified Δ , consider testing $H_0: \mu_1 = \mu_2$ against $H_1: \mu_1 - \mu_2 = \Delta (> 0)$ at a significance level α . If a right-tailed test is used to ensure power $1 - \beta$, then an allocation procedure targeting ρ in the limit, requires:

$$n = \left(\frac{\sigma_1^2}{\rho} + \frac{\sigma_2^2}{1-\rho} \right) \left(\frac{\tau_\alpha + \tau_\beta}{\Delta} \right)^2 \quad (11)$$

observations approximately to detect the difference Δ (referred to as type I sample size^[40]). Thus, n is inversely proportional to $|\Delta|$, that is, as the difference increases, more samples are needed to maintain the power requirement. But Eq. 11 ignores the actual randomization adopted in the trial and hence can be far from the actual number. However, a number of sample size formulae considering the actual randomization can be found in the study by Hu and Rosenberger.^[40] In practice, σ_1 and σ_2 are unknown and need to be replaced by their estimates. As an example consider the RSIHR allocation targeting $\rho = \frac{\sqrt{\mu_1}}{\sqrt{\mu_1} + \sqrt{\mu_2}}$. Then, we need approximately 201 observations for a test of $H_0: \mu_1 = \mu_2 = 0.4$ against $H_1: \mu_1 = 0.6, \mu_2 = 0.4$, when $\alpha = 0.05$ and $\beta = 0.10$.

CONCLUSION

This entry provides a very brief overview of the logistics and references of response-adaptive designs in some important directions. Naturally, many important aspects and details are not included in this entry. Booklength discussions^[40–42] on response-adaptive designs are a good source of knowledge on the topic. However, Atkinson and Biswas^[42] provided a detailed description of the development, logistics, and applications of almost all types of response-adaptive designs. Interested readers can go through any of these books for further exposure on this topic.

Placebo Effect

Abstract

Prior to the advent of modern medicine, many medications prescribed as a part of medical practice were subsequently found to be pharmacologically inert. This entry examines how despite this fact, people felt they were being helped by the drug, an occurrence known as the placebo effect. The entry also discusses the role of this effect in modern clinical trials.

INTRODUCTION

Prior to the advent of modern medicine, many medications prescribed as a part of medical practice were subsequently found to be pharmacologically inert. Despite this fact, such inactive medication, often referred to as a “placebo”—which literally means “I shall please”—appeared to be efficacious for a large number of medical problems. Shapiro^[1] has suggested that most medical practice prior to the 17th century was just an exploitation of this “placebo effect.” This is reflected in Mothby’s *New Medical Dictionary* written in 1785, which defined placebo as “a commonplace method or medicine.”^[2] Toward the end of the 18th century, when the medical community was starting to doubt the effectiveness of some commonly prescribed medications, the term placebo was viewed more derisively. For example, the 1811 edition of Harper’s *Medical Dictionary* defined placebo as “an epithet given to any medium adopted more to please than to benefit the patient.”^[3]

OVERVIEW

In the last 50 years or so, much has been learned and written about the construct known as the placebo effect. Much of this large body of knowledge about the effects of placebo has been gleaned from the use of placebo as a control in clinical trials. A response to placebo has been reported for diseases involving nearly all organ systems within the body. Satisfactory response to placebo has been reported to be at least 30% or more for a variety of disorders and often as high as 70%.^[4] This had led some in the medical community to recommend placebo as a legitimate form of treatment.^[5] Despite the amount of research on this phenomenon and the extensive reports of responses to placebo, there still is not a good understanding about the mechanism and causes of the placebo effect. In fact, there is still some

confusion and a lack of consensus on what constitutes the placebo and a placebo response.

Beecher^[6] defined the placebo as a pharmacologically inert substance. This is consistent with the definition given in Stedman’s *Medical Dictionary*, 26th edition,^[7] which appears as follows: (1) “an inert substance given as a medicine for its suggestive effect,” (2) “an inert compound identical in appearance to material being tested in experimental research, which may or may not be known to the physician and/or patient, administered to distinguish between drug action and suggestive effect of the material under study.” In a pharmacological setting, it is common to expand the first definition by equating an inert substance to all factors other than the active pharmacological agent. However, this definition implies that any form of specific nonpharmacological intervention, such as psychotherapy, is a form of placebo.

In order to avoid such erroneous classification, more expanded definitions of placebo attempt to differentiate between specific actions of an agent and its nonspecific effects, the latter being defined as placebos. Shapiro^[8] proposed a broad definition of placebo that includes nonpharmacological cases as well. He defines the placebo as any therapy (or component of therapy) that is deliberately or knowingly used for its nonspecific, psychological, or psychophysiological effect, or that is used unknowingly for its presumed or believed effect on a patient, symptom, or illness, but which, unknown to a patient and therapist, is without specific activity for the condition being treated. This definition encompasses the use of placebo as a control in clinical trials as well as a treatment in medical practice. However, classifying a therapy’s effect as nonspecific or specific is often difficult in practice, particularly when the therapy is nonpharmacological. This has led some authors to conclude that one cannot define placebo in a logically consistent way.^[9] Still others have proposed more elaborate and lengthy definitions that have attempted to avoid the alleged contradictions inherent in the specific and nonspecific distinction.^[10]

As a result of various definitions of placebo, there is also much lack of agreement on what a placebo effect is and what it is not. Some examples of definitions of the placebo effect are the following: (1) the improvement that occurs in a patient who is being treated with placebo;^[11] (2) a significant therapeutic response to “inert” or “placebo” substances;^[12] and (3) an effect that is produced by a medical procedure’s therapeutic intent and not its specific nature.^[13] What some authors consider factors or causes of the placebo effect others claim to be alternative effects that are not part of the placebo response. Because the focus of this entry is on pharmacological agents in clinical trials, placebo will be defined as simply an inert pill or injection masking as an active agent; correspondingly, the placebo effect will be defined as a therapeutic response to the treatment with placebo. Whereas items such as spontaneous remission (i.e., natural course of healing) and regression toward the mean would generally not be considered part of the placebo effect, we will consider such phenomena because they can play a key role in the observed improvement of placebo-treated subjects.

REGULATORY REQUIREMENTS

Before a new drug can be approved for use in nearly any country throughout the world, it must be demonstrated that it is safe and effective. For nearly 30 years, the Food and Drug Administration (FDA), through the Federal Register, has mandated that new drugs must be evaluated via randomized, blinded, controlled clinical trials. Similar requirements have been adopted by many other Western countries. To gain approval in the United States, a drug must be shown to be efficacious, usually in at least two adequate and well-controlled trials. Whereas the guidelines do not specifically mandate the use of placebo as a control, placebo usually is the standard for comparison. To demonstrate efficacy in a placebo-controlled trial, one has to show superiority to placebo; that is, the drug effect can add more to the underlying placebo effect. In many studies in which the placebo group has improved substantially, even drugs that are known to be efficacious do not show statistical superiority over placebo. For example, sertraline, a widely used efficacious drug for major depressive disorder (MDD) was found to be statistically superior to placebo in just two of the five placebo-controlled trials that were conducted in MDD as part of the approval process.^[14] In the last 17 years, there have been only two anxiolytics approved by the FDA. It is speculated that it is just too difficult to demonstrate superiority to placebo in generalized anxiety disorder, where the placebo response rate is notoriously high. Hence, it is assumed that if one could reduce the placebo response, it would be easier to demonstrate that an effective agent is superior to placebo. To that end, one first needs to consider the mechanisms that are associated with the placebo response.

FACTORS INFLUENCING THE PLACEBO RESPONSE

Factors and mechanisms associated with the placebo response can be crudely classified into two types:^[12] environmental factors and patient factors. The former includes the clinical setting, the attitude of the medical care personnel, and the expectation of the principle investigator. The latter refers to patient history, patient personality traits, and the patient’s experience and expectations. Environmental and patient factors are related, and their interaction in the form of a doctor–patient relationship can create a very important social psychological phenomenon that is thought to be highly influential on the placebo effect.

Clinical settings and medical practitioners that convey empathy, warmth, interest, and understanding are generally thought to contribute to nonspecific positive therapeutic response, especially in disorders in which the measures of response to treatment are more subjective. If the clinician has an enthusiastic attitude and a positive expectation, this is likely to increase the response to placebo. On the other hand, a practitioner or experimenter that shows aloofness, curttness, and pessimism will create an environment that will probably diminish the placebo effect.

Patient factors include personality, history, and demographic variables. Unlike the environmental factors, these items are generally not controllable. It has been stated by several researchers^[15]—with varying degrees of evidence—that patients that are more acquiescent and suggestible are more likely to respond to placebo. The patient’s expectations and attitude about the treatment, which are shaped to a large degree by a confluence of his or her personality and history, also are believed to be associated with the degree of placebo response. For example, patients who want to be in control are felt to be more likely to respond to placebo because the act of taking a pill is an action that will make them feel in charge. Intuitively, patients that have had favorable experiences with medication are thought to be more responsive to placebo. In contrast, patients that are highly skeptical of much of modern medicine or generally shun conventional medical treatment have been found to be placebo nonresponders.^[16] Conditioning, which can be influenced by experience and expectation, has also been implicated as a cause of the placebo effect. For example, airway resistance^[17] and gastric contractibility^[18] have been reported to be influenced by placebo. Other physiological variables that may be influenced by classical conditioning, and thus potentially be affected by placebo, include heart rate, blood pressure, EKG patterns, vasomotor activity, and the immune response.^[19,20] It has been reported that placebo has been found to produce endorphins in pain studies,^[21–23] although the validity of this finding has been challenged.^[4,24,25]

Bush^[16] has categorized factors that influence the placebo effect into two classes: “bound” and “manipulable.” Bound factors depend on the history and personality of the patient

and clinicians and are viewed as generally unalterable. Manipulable factors, which include most of the environmental factors discussed in the previous paragraph, are viewed as alterable to a large degree. Further examples of these factors include the shape, color, and characteristics of the active and placebo agents. Shapira et al.^[25] studied the use of oxazepam in either a green, yellow, or red tablet in 48 patients; they reported that green tablets tended to be more effective for anxiety, whereas yellow pills seemed to more effective for depressive symptoms. Blackwell et al.^[26] suggested that multiple pills and pills of larger size produced a larger placebo effect. Thomson^[27] insinuated that the “active placebo” (one that has similar side effects to the active agent it is to mimic) atropine amplified the placebo response in tricyclic-antidepressant trials.

STATISTICAL ISSUES

Factors Associated with the Placebo Response

Improvement in response to placebo does not imply that placebo or associated nonspecific effects have generated the therapeutic benefit. For example, improvement in some cases is the result of spontaneous remission. One very important factor that probably accounts for a large degree of the improvement in the placebo group in clinical trials is the phenomenon of regression toward the mean, which was first described by Galton.^[28] “Regression toward the mean” is the tendency for an extreme variable value to move closer to the mean when the variable is remeasured. McDonald and Mazzuca^[29] argued that much of the improvement observed in the placebo group in clinical trials is attributed to regression toward the mean. To explain regression toward the mean mathematically, let the random variables Y_1 and Y_2 represent some response variable for the same individual at two separate time points. Further, for the sake of simplicity, assume that the joint distribution of Y_1 and Y_2 is bivariate normal with a common mean μ , common variance σ^2 , and correlation coefficient ρ . Then

$$E(Y_2 - Y_1 | Y_1 = y_1) = (\mu - y_1)(1 - \rho)$$

Note that if $y_1 > \mu$, then $E(Y_2 - Y_1) < 0$; moreover, the expected decrease from the first measure to the second is proportional to $|\mu - y_1|$, i.e., to how extreme the first value is. This expected decrease (when $y_1 > \mu$) is also proportional to $1 - \rho$; hence one would expect a larger decrease as the correlation becomes less positive (repeated measures on the same individual are almost always positively correlated). As a result, outcome variables that are less reliable—or reproducible—will be more prone to the effects of regression toward the mean.

Because detailed information concerning μ , σ^2 , and ρ for many laboratory variables is available in the

medical literature, McDonald and Mazzuca^[29] calculated the expected change in a repeat measure when the first measure was greater than $\mu + 3\sigma$. For 15 laboratory variables, they found the expected decrease ranged from 2.5% to 26%, which agreed well with empirical data from 12,000 patients obtained via hospital medical records.

Since entrance criteria for clinical trials are usually based on the subject's presenting either a high or low value at baseline, regression toward the mean is likely to explain a large degree of the improvement observed in clinical trials, particularly when the response variable is fairly subjective and not highly reliable.

When the outcome variable is rather subjective, observer bias is another factor that could potentially contribute to the improvement attributed to placebo. This factor has been largely ignored in the plethora of literature about the placebo response. Indications of observer bias appear in the data from clinical trials that incorporate a single-blind placebo run-in phase (this design feature will be discussed further in the next section) in order to screen for “placebo responders” prior to randomization into the double-blind phase of the study.^[30] It has been the authors' experience, based on many placebo-controlled trials using placebo run-ins, that the degree of improvement on the average (or the percentage of “responders”) during this initial phase is generally far less than that experienced by the patients randomized to placebo during a comparable period of time within the double-blind portion of the study. Whereas this observation could in part be due to regression toward the mean, there may be an upward bias in the measurements (i.e., more abnormal) at the end of the single-blind placebo phase of the trial for two reasons: First, the observer or investigator knows the subjects are receiving placebo; second, there may be incentive for the investigative site to reach their recruitment goals. On the other hand, during the double-blind portion, there may be a bias toward more improved measures or ratings because the investigator may speculate that the subject is on an effective medication and hence is expecting an improvement.

Design Considerations

One design feature frequently incorporated into clinical trials (e.g., hypertension and psychopharmacology trials), as already mentioned, is the use of a single-blind placebo run-in. One of the main purposes of this run-in phase is to screen out subjects that show a substantial improvement with placebo. Despite the lack of critical review of such a design, a placebo run-in is almost always used in depression studies. The few investigations that have attempted to assess this design have generally not found the placebo run-in to be effective at reducing the placebo response rate.^[30] Trivedi and Rush^[31] conducted a meta-analysis on 101 blinded placebo-controlled depression studies that were conducted from 1959 to 1990. After cross-classifying the trials by the type of active drug (i.e., tricyclics,

monoamine oxidase inhibitors, and serotonin reuptake inhibitors) and whether they were outpatient or inpatient, they found few statistically significant differences in the placebo response rates between trials that had a run-in and those that did not.

Regression toward the mean is one reason that the placebo run-in appears not to be effective at reducing the response to placebo. Subjects are still entered into the study on the basis of having an extreme baseline value for the response of interest. In the absence of other reasons for extreme baseline values, such as observational bias, one approach to minimize the effects of regression toward the mean would be to take multiple measurements during a screening period. These measures could then be averaged to obtain a baseline value. Another approach would be to take two “baseline” measurements (that would perhaps be at least within a week of each other): The first would be used for determining eligibility (i.e., the subjects would have to meet some criterion for disease severity) and the other used as the baseline measurement for the purpose of calculating change.

As previously implied, observational bias may be another reason that single-blind placebo run-ins may not be useful at reducing the placebo effect. In studies in which the primary outcome variable is subjective, one possible design that would address observational bias would be one that had a random-length double-blind placebo run. One could perceive of many variations of such a design. One possibility for comparing one active agent to placebo is as follows: After a 1-week single-blind placebo period, subjects still meeting the eligibility criterion (i.e., an extreme value for the outcome of interest) would be randomized in double-blind fashion to placebo (95% of the subjects) or active drug (5% of the subjects). After a 1-week period (and a clinical assessment), half of the placebo subjects would be randomized to placebo while the other half continues to receive placebo. The primary analysis for efficacy would include only those subjects randomized at week 2 that still continued to meet the entrance criterion. Week 2 would be considered baseline. One could also conduct a secondary analysis that would include all randomized subjects (week 1 would be considered baseline for the 5% of the subjects randomized to active drug at week 1; week 1 might also be considered to be the baseline for all other subjects in such a secondary analysis). This design, as well as variations of a random-length placebo period, would probably be even more effective at reducing observational bias if the precise nature of the run-in and the data analysis were not completely spelled out in the protocol. Although this may cause some ethical and logistic concerns, it might be sufficient just to state in the protocol that a randomization to the two treatments will occur over several weeks. The details of the planned analysis could be contained in another document, separate from the procedures of the protocol.

There is yet another way to reduce observational bias in outcomes that are measured on some type of calibrated instrument (e.g., sphygmomanometer, spectrophotometer, scales for weight): Recalibrate in such a way that one randomly sets the “zero mark.” For instance, a diastolic blood pressure of 80 mm Hg would appear as 100 on an sphygmomanometer in which zero was set at 20. Such tactics would be most useful for reducing observational bias in single-blind studies.

ATTEMPTS AT PREDICTING PLACEBO RESPONSE IN DEPRESSION

In much of clinical research, particularly in psychopharmacology, there is a perception that the placebo response is becoming more pronounced,^[32] which has led many researchers to believe that it is becoming increasingly more difficult to demonstrate the efficacy of new medications. By the nature of clinical trials, usually it is implicitly assumed that the placebo effect and the therapeutic effect of an active medication are additive, but this may not be the case in many instances, particularly when the placebo effect is large and there is a ceiling effect on the degree of improvement. While there has been a large amount published about qualitatively describing “placebo responders,” only in the last decade or so has there been much effort at attempting to predict placebo response on an individual basis based on screening information.^[33–39] If one could predict placebo response based on demographic or medical history information, then one could exclude likely “placebo responders” prior to entry into the study. Most of these efforts at finding predictors of placebo response in psychiatric disorders have entailed retrospective, exploratory analyses of small data sets comprised of one to a few studies. As a result, there has been a smattering of reports of “statistically significant” differences between “placebo responders” and nonresponders from one investigation to another but limited agreement among the reports. Following are some of the variables that have been cited from two or more published studies as being related to placebo response in depression. The likelihood of being a placebo responder increases as (1) the duration of the current episode decreases, (2) the degree of precipitating stress increases, and (3) the number of previous treatments for depression decreases.

In unpublished research conducted by these authors and colleagues, an artificial neural network (ANN) was trained (using a data set containing patients from four depression studies) to predict which subjects—based on some of the variables listed previously as well as others—would respond to placebo (experience a 50% or more decrease in the Hamilton Depression Rating Scale). Whereas the ANN seemed to have some success for predicting placebo response, it did not appear to enhance the difference between the active drug and placebo. In fact, removing

the predicted “placebo responders” from the analysis of a validation data set decreased the average improvement of the active drug more than that of the placebo group. This effect has also been reported by Reimherr et al.^[30] In depression, this suggests that “placebo responders” also show a large response to active drug and that removal of such subjects leaves a population of subjects that are in general more treatment resistant. For a binary outcome, it has been speculated by Day^[40] that in some instances there may be an optimal level of placebo response for the purpose of detecting a difference between placebo and active drug. For example, the placebo response and the therapeutic effect due to active drug might be additive on a logistic scale. If the true odds ratio between active and placebo is 3.86, then increasing the placebo response from 0.1 to 0.2 results in an increase in the active drug response from 0.3 to 0.49. It is also possible in certain cases that the “placebo response” and the “therapeutic response” might be more than just additive on measurement scales that are commonly used for continuous outcomes.

Abstract

As more and more generic drug products become available in the market place, there are increasing concerns over whether generic drugs approved based on the current regulation of average bioequivalence (ABE) have the same quality, safety, and efficacy profiles as brand-name drug products. This entry provides several statistical models for determining population bioequivalence.

INTRODUCTION

Bioequivalence studies are conducted to demonstrate equivalence in the bioavailability of the active ingredient in different formulations. The U.S. Food and Drug Administration (FDA) requires pharmaceutical companies to show bioequivalence between different formulations or generic companies between generic drugs and brand drugs before approval. A recent FDA guidance on bioequivalence proposes criteria for assessment of population bioequivalence (PBE) and individual bioequivalence (IBE). This article introduces the background and methods for testing PBE.

In recent years, generic medicines have played an increasingly important role in the efforts to contain the costs of medicines. As more and more generic drug products become available in the market place, there are increasing concerns over whether generic drugs approved based on the current regulation of average bioequivalence (ABE) have the same quality, safety, and efficacy profiles as brand-name drug products.

OVERVIEW

In the U.S. 21 Code for Federal Regulation (CFR) 320.1, bioequivalence is formally defined as “the absence of a significant difference in the rate and extent to which the active ingredient or active moiety in pharmaceutical equivalents or pharmaceutical alternatives becomes available at the site of drug action when administered at the same molar dose under similar conditions in an appropriately designed study.” In 1992, in order to meet these provisions, the U.S. FDA issued an official guidance titled *Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design*.^[1] According to this

guidance, in order to establish that two drugs are bioequivalent, it is only necessary to demonstrate that two drugs are similar in average bioavailability in terms of pharmacokinetic parameters such as AUC or $C_{\max}$. From a statistical point of view, this similarity in average bioavailability, often termed average bioequivalence, considers only the population means, but ignores the variability of pharmacokinetic parameters across different subject populations or across multiple measurements from the same subject. Hence, there are concerns that this approach may not guarantee that the two drugs are similar in all or even most individual subjects in the intended patient populations.^[2,3]

Anderson and Hauck^[4,5] first introduced the terms “population bioequivalence” and “individual bioequivalence” to address these concerns. Since then, extensive research results are available on the criteria as well as the associated procedures for establishing these kinds of bioequivalence (see, e.g., Refs. [6–8]). In 1995, the FDA formed a bioequivalence working group to investigate these issues. As a result of this effort, the FDA issued a preliminary draft guidance titled *In Vivo Bioequivalence Studies Based on Population and Individual Bioequivalence Approaches*.^[9] Based on public comments, the FDA issued a revised draft guidance titled *Average, Population, and Individual Approaches to Establishing Bioequivalence*.^[10] This draft guidance proposed mixed-scaled aggregate criteria for population bioequivalence and individual bioequivalence, with bootstrap-based^[9] and moment-based^[10] methods for testing of these criteria. In January 2001, the FDA issued a final guidance entitled *Statistical Approaches to Establishing Bioequivalence*.^[11] This guidance replaced the previous draft guidance and the 1992 FDA bioequivalence guidance. In addition, the FDA issued another draft guidance entitled *Bioavailability and Bioequivalence Studies for Nasal Aerosols and*

Nasal Sprays for Location Reaction,^[12] which also calls for population bioequivalence.

This encyclopedia entry focuses on population bioequivalence. Topics related to individual bioequivalence are addressed in a separate entry by Chow and Liu (see *Individual Bioequivalence*). The next section reviews and discusses the FDA 2001 guidance with respect to population bioequivalence. The section “Statistical Analysis” covers the statistical analysis for population bioequivalence. The last section provides general discussions and comments.

POPULATION BIOEQUIVALENCE REGULATORY REVIEW

Population Bioequivalence Concept

One of the key concerns on average bioequivalence is whether it can guarantee drug interchangeability. Population bioequivalence and individual bioequivalence address drug interchangeability under two different clinical situations. Population bioequivalence refers to the interchangeability for a patient who has not previously received either test or reference drug, and is about to receive one or the other, whereas individual bioequivalence refers to interchangeability for a patient who switches from a reference drug to a test drug.^[4]

To guarantee population bioequivalence of test and reference drugs, the population distribution of the pharmacokinetic measurements for test and reference drugs should be similar when these drugs are administered to new or drug-naïve patients. Under the normality assumption, not only the population average but also the overall variability of the pharmacokinetic measurements for test and reference drugs should be similar. To quantify the similarity, the FDA 2001 guidance adopted the notion of population difference ratio (PDR), which measures the ratio of the expected squared difference between test and reference drugs to the expected squared differences between two administrations of reference drugs, when these drugs are given to drug-naïve patients. The PDR can be written as:

$$\text{PDR} = \sqrt{\frac{E(T-R)^2}{E(R-R')^2}} \quad (1)$$

Conceptually, a test drug (T) is population bioequivalent to a reference drug (R) if the PDR is within an acceptable limit. Based on this important concept, the FDA population bioequivalence criterion (PBC) can be formulated and tested under different statistical models and study designs.

Statistical Model

Statistical analyses of bioequivalence data are typically based on a statistical model for the logarithm of the

pharmacokinetic measures (e.g., AUC and $C_{\max}$). Most of the statistical models proposed for bioequivalence assessment are linear mixed-effects models, which usually include fixed effects such as treatment, sequence, and period, as well as random effects of subjects. Under a conventional 2×2 crossover design, the following linear mixed-effects model or some variations of this model are typically used for bioequivalence analysis:^[4,13,14]

$$Y_{ijk} = \mu + s_{ij} + \pi_j + \tau_k + \varepsilon_{ijk} \quad (2)$$

$$i = 1, \dots, n; j = T, R; k = 1, 2$$

In Eq. 2, Y_{ijk} is the log-transformed pharmacokinetic response of the i th subject on drug j in the k th sequence, μ represents the overall mean, (s_{iT}, s_{iR}) is independently distributed normal random vector for subject i with mean

$$\begin{pmatrix} 0 \\ 0 \end{pmatrix}$$

and covariance matrix

$$\begin{pmatrix} \sigma_{BT}^2 & \rho\sigma_{BT}\sigma_{BR} \\ \rho\sigma_{BT}\sigma_{BR} & \sigma_{BR}^2 \end{pmatrix}$$

π_j is the fixed effect of the drug j (where $\pi_1 + \pi_2 = 0$), τ_k is the fixed effect for sequence (where $\tau_1 + \tau_2 = 0$), and ε_{ijk} are independent normal random variables with mean 0 and variance σ_{wj}^2 ($j = T, R$).

In this model, each subject has subject-specific means of $\mu + s_{iT} + \pi_T + \tau_k$ and $\mu + s_{iR} + \pi_R + \tau_k$ for the test and reference drugs, respectively. Ignoring the sequence effect, the model assumes that these subject-specific means come from a distribution with population means μ_T and μ_R with respective between-subjects variances of σ_{BT}^2 and σ_{BR}^2 . The total population variances for the test and reference drugs (σ_{TT}^2 and σ_{TR}^2 , respectively) are summations of between-subjects variances and within-subject variances (σ_{WT}^2 , σ_{WR}^2). Similar models can be used for repeated crossover design.

Bioequivalence Criterion

The 1992 and 2001 guidances recommend the following criterion for average bioequivalence:

$$-\theta_A \leq \mu_T - \mu_R \leq \theta_A$$

where the bioequivalence limit (θ_A) is usually set at $\ln(1.25)$.

Conceptually, as described in the section “Population Bioequivalence Concept,” the PDR should be controlled by a specified limit to guarantee population bioequivalence. Based on this concept, the 2001 guidance proposes the following mixed-scaling population bioequivalence criterion:

$$\text{PBC} = \frac{(\mu_T - \mu_R)^2 + (\sigma_{TT}^2 - \sigma_{TR}^2)}{\max(\sigma_{T0}^2, \sigma_{TR}^2)} < \theta_p \quad (3)$$

where σ_{T0}^2 is a specified scaling constant for total variance and θ_p is the population bioequivalence limit. This criterion is equivalent to the following linearized criteria:

$$\begin{aligned}\eta_1 &= (\mu_T - \mu_R)^2 + (\sigma_{TT}^2 - \sigma_{TR}^2) - \theta_p \sigma_{TR}^2 < 0, \\ &\text{for } \sigma_{TR} > \sigma_{T0} \quad \text{reference - scaling} \\ \eta_2 &= (\mu_T - \mu_R)^2 + (\sigma_{TT}^2 - \sigma_{TR}^2) - \theta_p \sigma_{T0}^2 < 0, \\ &\text{for } \sigma_{TR} \leq \sigma_{T0} \quad \text{constant - scaling}\end{aligned}\quad (4)$$

The mixed-scaling strategy is proposed in consideration of different drug variability and different therapeutic window. Reference scaling can effectively loosen the population bioequivalence criteria for more variable reference products (i.e., $\sigma_{TR} > \sigma_{T0}$). Constant scaling is recommended for drug products that have a wide therapeutic window and low variability (i.e., $\sigma_{TR} \leq \sigma_{T0}$), to avoid unnecessarily tightening its population bioequivalence criteria. An exception is narrow therapeutic window drugs or drug products, where reference scaling is recommended regardless of the reference variability.

Note that under reference scaling, PBC is monotonically related to PDR: $PDR = [(PBC/2) + 1]^{1/2}$. Based on the consideration of a maximum allowable PDR of 1.25, the 2001 guidance recommends that scaling constant of 0.2 (i.e., $\sigma_{T0} = 0.2$). The guidance also suggests that the population bioequivalence limit θ_p be chosen as

$$\theta_p = \frac{(\ln 1.25)^2 + \varepsilon_p}{\sigma_{T0}^2}$$

where the value of ε_p for population bioequivalence is guided by the consideration of the variance term ($\sigma_{TT}^2 - \sigma_{TR}^2$) added to the average bioequivalence criterion.

Study Design

For the purpose of establishing bioequivalence between a test (T) and a reference (R) drug, the FDA recommends a standard two-sequence two-period in vivo bioequivalence study design (TR/RT) in its July 1992 guidance on *Statistical Procedures for the Bioequivalence Studies Using a Standard Two-Treatment Crossover Design*.^[1] In the 2001 guidance, the FDA points out that conventional 2×2 crossover design, as well as replicated crossover design, can be used for testing of ABE and PBE. For example, the 2001 FDA guidance illustrates the testing for population bioequivalence under the four-period, two-sequence, two-drug study design could be TRTR/RTRT.

Use of crossover designs for bioequivalence studies allows each subject to serve as his or her own control to improve the precision of the comparison. However, one of the assumptions underlying this principle is that carryover effects are either absent or equal for both drugs. In most cases (for both replicated and conventional crossover designs), the inequality of carryover effects is considered

unlikely in a bioequivalence study. If sponsors suspect the carryover effects might be an issue, the 2001 guidance recommends the BE study with parallel design.^[11]

Sample Size Calculation

According to the FDA guidance,^[11] a minimum number of 12 subjects should be included in any bioequivalence study. When an average bioequivalence criterion is selected using either nonreplicated or replicated designs, published formulas can be used to determine the sample size for average bioequivalence.^[14] Because analytical approaches for population bioequivalence estimation are not available, sample size for the population bioequivalence should be estimated by simulation. The simulations should be conducted using a default situation allowing the two drugs to vary as much as 5% in average bioequivalence with equal variances. The study should have 80% or 90% power to conclude bioequivalence between these two drugs.^[11]

STATISTICAL ANALYSIS

General Background

For average bioequivalence, the 1992 guidance and the 2001 guidance recommend that statistical analysis for pharmacokinetic parameters be based on the Schuirman's two one-sided test procedure.^[15] To establish bioequivalence, the calculated 90% confidence interval for the ratio of product averages in the original scale should fall within 80–125%. Equivalently, the calculated 90% confidence interval for the difference between two product averages in log scale should fall within $\ln(0.8)$ and $\ln(1.25)$. Chow and Liu^[14] give an excellent overview of average bioequivalence.

The FDA 2001 guidance^[11] proposes a method based on moment estimators of variance components to evaluate population bioequivalence. Before method of moments was introduced, population bioequivalence was evaluated using bootstrap approach with restricted maximum likelihood (REML) estimators under a mixed-effects model. However, there are some concerns in using the bootstrap to determine whether a new drug provides population bioequivalence. One concern is that bootstrap does not provide a unique solution. For example, if a sponsor submits a package and claims population bioequivalent based on the sponsor's bootstrap data, FDA may run a bootstrap using a different seed. With the new bootstrap, the FDA finds that the submitted drug is not population bioequivalent. In this dilemma, how can the final decision be made?

Therefore, nonbootstrap methods are developed recently to evaluate population bioequivalence (see, e.g., Refs. [11,16,17]). Most of these methods are based on moment estimators, and they are confidence interval approaches using the modified large sample (MLS) concept.^[18]

As discussed earlier, FDA considers the use of bioequivalence criteria in Eq. 3 to determine population bioequivalence. Bioequivalence can be concluded if the null hypothesis (H_0) below is rejected at a given Type I error (α):

$$H_0 : \text{PBC} \geq \theta_p \quad \text{vs.} \quad H_a : \text{PBC} < \theta_p$$

Under this setting, the one-sided upper $(1 - \alpha) \times 100\%$ confidence bound U can be used to test the hypothesis—that is, if $U < \theta_p$, then population bioequivalence can be concluded. On the other hand, $U \geq \theta_p$, leads to accepting H_0 and population bioequivalence is rejected.

Based on model Eq. 2 under a 2×2 crossover design, the sums of squares and mean squares can be formulated as follows:

Source of Variation	SS	df	MS	E(MS)
Drug	$SS_D = \sum_i \sum_j \sum_k (Y_{ijk} - \bar{Y}_{i..})^2$	1	S_D^2	θ_D
Intrasubject	$SS_I = \sum_i \sum_j \sum_k (Y_{ijk} - \bar{Y}_{.j.})^2$	$2(n-1)$	S_I^2	θ_I
Treatment R	$SS_{TR} = \sum_i (Y_{i11} - \bar{Y}_{.11})^2 + \sum_i (Y_{i12} - \bar{Y}_{.12})^2$	$2(n-1)$	S_{TR}^2	θ_{TR}
Treatment T	$SS_{TT} = \sum_i (Y_{i21} - \bar{Y}_{.21})^2 + \sum_i (Y_{i22} - \bar{Y}_{.22})^2$	$2(n-1)$	S_{TT}^2	θ_{TT}

In general, these θ_i s are referred to as variance components, SS denotes sum of squares, df stands for degrees of freedom, MS represents mean square, and E(MS) denotes expected value of mean square. It can be shown that SS_I/θ_I , SS_{TT}/θ_{TT} , SS_{TR}/θ_{TR} , are all χ^2 random variables with $2(n-1)$ degrees of freedom, and SS_D/θ_I is a noncentral χ^2 random variables with noncentrality parameter λ . The population bioequivalence criteria in Eq. 3 can then be expressed in terms of variance components (θ_i s) as

$$\begin{aligned} \text{PBC} &= \frac{(\theta_D - \theta_I)/n + \theta_{TT} - \theta_{TR}}{\theta_{TR}} \quad \text{if } \sigma_{TR}^2 > \sigma_{T0}^2 \\ \text{PBC} &= \frac{(\theta_D - \theta_I)/n + \theta_{TT} - \theta_{TR}}{\sigma_{T0}^2} \quad \text{if } \sigma_{TR}^2 \leq \sigma_{T0}^2 \end{aligned} \quad (5)$$

Howe^[19] developed an extension of the Cornish–Fisher expansion to compute percentiles for the sum of two random variables. Howe's idea was later used to develop confidence intervals on various functions of variance components. For example, methods developed for sums (see, e.g., Ref. [20]), linear combinations,^[21] and ratio of variance components^[22] are introduced in the book by Burdick and Graybill.^[18] These methods are generally referred to as the MLS methods. The general idea for constructing a $(1 - \alpha) \times 100\%$ confidence interval for θ ($\theta = \sum_i c_i \theta_i$), a linear function of variance components, is to use the moment estimator $\hat{\theta}$ as the point estimate for θ , and then add and subtract the square root of a function of variance estimator for components of θ , together with quantile points F_i^*

from F distributions, to approximate the upper and lower confidence bounds such that

$$P \left[\hat{\theta} - \sqrt{\sum_i f_i(c_i^2 \hat{\theta}_i^2, F_i^*)} \leq \theta \leq \hat{\theta} + \sqrt{\sum_i g_i(c_i^2 \hat{\theta}_i^2, F_i^*)} \right] \geq 1 - \alpha$$

The FDA 2001 Method

The FDA 2001 guidance extends a method developed by Hyslop et al.^[13] for the evaluation of individual bioequivalence to solve the population bioequivalence problem. However, that method is not directly applicable to population bioequivalence testing due to the violation of a primary assumption of independence among the estimated components (as pointed out in Ref. [17]).

The method mentioned in the 2001 FDA Guidance is based on a two-sequence, four-period (2×4) crossover design. With some minor modifications, this method can be expressed in a 2×2 design. After converting Eq. 5 into a linear form, it follows that

$$\begin{aligned} \frac{(\theta_D - \theta_I)/n + \theta_{TT} - \theta_{TR}}{\theta_{TR}} &\Rightarrow \eta_1 \\ &= (\theta_D - \theta_I)/n + \theta_{TT} - (1 + \theta_p)\theta_{TR} \end{aligned}$$

and

$$\begin{aligned} \frac{(\theta_D - \theta_I)/n + \theta_{TT} - \theta_{TR}}{\sigma_{T0}^2} &\Rightarrow \eta_2 \\ &= (\theta_D - \theta_I)/n + \theta_{TT} - \theta_{TR} - \theta_p \sigma_{T0}^2 \end{aligned}$$

The population bioequivalence can be evaluated in the following steps:

1. Compute S_{TR}^2 .
2. If $S_{TR}^2 > \sigma_{T0}^2$, construct a $(1 - \alpha) \times 100\%$ upper confidence bound for the linearized function η_1 using

$$U_{R1} = S_D^2/2n + S_{TT}^2 - (1 + \theta_p)S_{TR}^2 + \sqrt{V_{R1}}$$

where

$$\begin{aligned} V_{R1} &= (H_D - E_D)^2 + (1/F_L - 1)^2 S_{TT}^4 + (1 + \theta_p)^2 \\ &\quad (1 - 1/F_U)^2 S_{TR}^4, \quad H_D = \left\{ \sqrt{E_D} + t_{1-\alpha; 2(n-1)} \sqrt{S_I^2/n} \right\}^2, \quad E_D = \\ &\quad S_D^2/n, \quad F_L = F_{1-\alpha; 2(n-1), \infty}, \quad F_U = F_{\alpha; 2(n-1), \infty} \cdot F_{\alpha; df1, df2} \end{aligned}$$

represents the F value with $df1$ as the degrees of freedom in the numerator and $df2$ the degrees of freedom in the denominator, with area α to the right. $t_{1-\alpha; 2(n-1)}$ is the t value with degrees of freedom $2(n-1)$ and area α to the right.

3. If $S_{TR}^2 \leq \sigma_{T0}^2$, construct an upper bound for the linearized function η_2 using

$$U_{C1} = S_D^2/n + S_{TT}^2 - S_{TR}^2 - \theta_p \sigma_{T0}^2 + \sqrt{V_{C1}}$$

where

- $V_{C1} = (H_D - E_D)^2 + (1/F_L - 1)^2 S_{TT}^4 + (1 - 1/F_U)^2 S_{TR}^4$.
4. Reject $H_0: \theta_{PBE} \geq \theta_p$ and claim population bioequivalent if the computed upper bound is < 0 .

The above four steps summarize the FDA method for the evaluation of population bioequivalence.

In addition to the FDA method, a few, newer methods were recently developed. Two of these new methods are introduced in the following subsections. One is an alternative MLS method that preserves the ratio form of the population bioequivalence criteria [without linearization^[16]]. The other method is proposed to deal with the correlation among the estimated variance components.^[17]

An Alternative Modified Large Sample Method

Lu et al.^[22] propose an MLS confidence interval on $(a\theta_1 - b\theta_2)/\theta_3$. In a recent paper by Quiroz et al.,^[16] a method to evaluate population bioequivalence is proposed by applying the method by Lu et al.^[22] for the referenced scale criterion and applying the method by Ting et al.^[21] for the constant scaled criterion. The approach by Quiroz et al. first converts the noncentral χ^2 variable SSD/θ_1 into a central χ^2 variable with n^* degrees of freedom, where $n^* = (1 + 2\hat{\lambda})^2/(1 + 4\hat{\lambda})$, and $\hat{\lambda} = n(\bar{Y}_R - \bar{Y}_T)^2/2S_1^2$. Then the χ^2 variables are combined to fit the form $(a\theta_1 - b\theta_2)/\theta_3$.

Let $\theta_{DT} = \theta_D/n + \theta_{TT}$ and $\theta_{IR} = \theta_I/n + \theta_{TR}$, based on Satterthwaite.^[23] Then $n_{DT} S_{DT}^2/\theta_{DT}$ has an approximate χ^2 distribution with n_{DT} degrees of freedom (df), and $n_{IR} S_{IR}^2/\theta_{IR}$ has an approximate χ^2 distribution with n_{IR} df , where $S_{DT}^2 = S_D^2/n + S_{TT}^2$, $S_{IR}^2 = S_I^2/n + S_{TR}^2$,

$$n_{DT} = \frac{S_{DT}^4}{(S_D^4/n^2 n^*) + (S_{TT}^4/n_{TT})}, \quad n_{IR} = \frac{S_{IR}^4}{(S_I^4/n^2 n_1) + (S_{TR}^4/n_{TR})}$$

and $n_{TR} = n_{TT} = n_1 = 2(n - 1)$.

Now the reference-scaled PBC can be rewritten as $(\theta_{DT} - \theta_{IR})/\theta_{TR}$. Using this approach, the resulting $1 - \alpha$ upper bound for PBC is

$$U_{R2} = \begin{cases} K_0 \hat{\rho} + \sqrt{V_{U1}}/S_{TR}^2 & \text{if } T \leq F_{L1} \\ K_0 \hat{\rho} + \sqrt{V_{U2}}/S_{TR}^2 & \text{if } T > F_{L1} \end{cases}$$

where

$K_0 = 1 - 2/n_{TR}$	$\hat{\rho} = (S_{DT}^2 - S_{IR}^2)/S_{TR}^2$	$T = S_{DT}^2/S_{TR}^2$
$V_{U1} = K_1 S_{DT}^4 + K_2 S_{IR}^4$	$V_{U2} = K_3 S_{DT}^4 + K_4 S_{IR}^4$	$K_1 = [K_0(1/F_{L1} - 1)]^2 - K_2/F_{L1}^2$
$K_2 = (K_0 - 1/F_{U1})^2$	$K_3 = (1/F_{L2} - K_0)^2$	$K_4 = [K_0(1 - F_{L1})]^2 - K_3 F_{L1}^2$
$F_{L1} = F_{1 - \alpha; n_{DT}, n_{IR}}$	$F_{L2} = F_{1 - \alpha; n_{DT}, n_{TR}}$	$F_{U1} = F_{\alpha; n_{IR}, n_{TR}}$

Again, the notation $F_{\alpha; df1, df2}$ represents the F value with degrees of freedom $df1$ in the numerator and $df2$ in the denominator, with area α to the right. For the constant

scale form PBC, a confidence interval on $\theta_{DT} - \theta_{IR}$ can be constructed using the Ting et al.^[21] method:

$$U_{C2} = \left(S_{DT}^2 - S_{IR}^2 + \sqrt{H_1^2 S_{DT}^4 + G_2^2 S_{IR}^4 + H_{12} S_{DT}^2 S_{IR}^2} \right) / \sigma_{T0}^2$$

where $H_1 = 1/F_{1 - \alpha; n_{DT}, \infty} - 1$, $G_2 = 1 - 1/F_{\alpha; n_{IR}, \infty}$, and $H_{12} = [(1 - F_{L1})^2 - H_1^2 F_{L1}^2 - G_2^2]/F_{L1}$.

The Quiroz et al.^[16] method for testing hypotheses concerning θ_{PBE} is:

1. Compute S_{TR}^2 .
2. If $S_{TR}^2 > \sigma_{T0}^2$, construct an upper bound using U_{R2} .
3. Otherwise, using U_{C2} .
4. Reject $H_0: PBC \geq \theta_p$ and claim population bioequivalence if the computed upper bound is less than θ_p .

Another New Method That Considers Correlation Among Variance Components

Chow, Shao, and Wang^[17] propose a new method to evaluate population bioequivalence. They consider the dependence among the chi-square random variables and include a covariance structure in the estimate. In their method, the upper bound for the reference scaled criterion is

$$U_{R3} = \hat{\delta}^2 + S_{TT}^2 - (1 + \theta_p) S_{TR}^2 + t_{1 - \alpha, 2(n-1)} \sqrt{V_{R3}}$$

where

$$\begin{aligned} \hat{\delta} &= \frac{1}{2} (\bar{Y}_{21} - \bar{Y}_{12} - \bar{Y}_{11} + \bar{Y}_{22}), \\ V_{R3} &= (2\hat{\delta}, 1, -(1 + \theta_p)) C (2\hat{\delta}, 1, -(1 + \theta_p))', \\ C &= \begin{pmatrix} \hat{\sigma}_{1,1}^2/2n & (0,0) \\ (0,0)' & (C_1 + C_2)/(4n - 4) \end{pmatrix} \end{aligned}$$

C_1 is the sample covariance matrix of $((Y_{i11} - \bar{Y}_{*11})^2, (Y_{i21} - \bar{Y}_{*21})^2)$, C_2 is the sample covariance matrix of $((Y_{i22} - \bar{Y}_{*22})^2, (Y_{i12} - \bar{Y}_{*12})^2)$, $i = 1, \dots, n$ and

$$\hat{\sigma}_{1,1}^2 = [1/(2n - 2)] \sum_{k=1}^2 \sum_{i=1}^n (Y_{ik1} - Y_{i2k} - \bar{Y}_{*1k} + \bar{Y}_{*2k})^2$$

The upper bound for the constant scaled criterion is:

$$U_{C3} = \hat{\delta}^2 + S_{TT}^2 - S_{TR}^2 - \theta_p \sigma_{T0}^2 + t_{1 - \alpha, 2(n-1)} \sqrt{V_{C3}}$$

where $V_{C3} = (2\hat{\delta}, 1, -1) C (2\hat{\delta}, 1, -1)'$

Regarding the choice of U_{R3} or U_{C3} , the authors suggest to perform a hypothesis test to observe if S_{TR}^2 is $> \sigma_{T0}^2$. This test is performed by comparing $S_{TR}^2/\chi_{\alpha; 2(n-1)}^2$ with σ_{T0}^2 . If $S_{TR}^2/\chi_{\alpha; 2(n-1)}^2 \geq \sigma_{T0}^2$, then the upper bound is constructed using U_{R3} . Otherwise U_{C3} is used.

One advantage of this method is that it can be applied to unbalanced cases, that is, when there are different numbers

of subjects in sequence 1 and sequence 2. Furthermore, methods proposed by Chow et al.^[17] are also available for 2×3 designs and 2×4 designs.

CONCLUSION

The methodological development of nonbootstrap methods by Hyslop et al.,^[13] Quiroz et al.,^[16] and Chow et al.^[17] have made the implementation of population bioequivalence testing more feasible. All these MLS methods avoid the problems suffered by the bootstrap method, which was originally proposed by the FDA in its early draft guidance for PBE and IBE. The MLS methods can perform population bioequivalence testing quickly with very moderate programming work. In addition, they also provide an effective mean for sample size assessment via simulation, which is almost impossible to do by the bootstrap method because of the sheer amount of computing time required. The performance of each MLS method was studied via simulation by its set of authors in terms of the Type I error or the coverage of the one-sided 95% confidence interval for the values of criteria in Eq. 4.^[13] Certain authors also performed simulation to study the power of their method and the FDA method for claiming population bioequivalence.^[16,17] In summary, all authors claimed the validity of their own methods. The interested readers should be referred to the articles listed in the references for further reading.

Although the major technical difficulties for population bioequivalence testing have been largely resolved by the development of the MLS methods. The controversies are still reverberating. The major division among the pharmaceutical industry, the regulatory agencies, and the academic community is on the necessity for amending the existing average bioequivalence criterion. Even though the concept of prescribability is laudable, the deficiency of average bioequivalence is yet evident. In other words, there are no or little evidences reported so far showing that a commercial formulation or a generic drug is either not safe or not efficacious although it was shown to be average bioequivalent to the formulation or the brand drug that was carefully studied in the clinical development. Many people strongly believe that the criterion of average bioequivalence is still adequate to protect consumers' interest for the most time. The compatibility of variability in the key pharmacokinetic parameters between two drugs is a valid concern and it is not reflected in the average bioequivalence criterion. Nonetheless, people still question whether the proposed population bioequivalence criterion is a good solution.

In the statistical community, people see the development in bioequivalence criteria as an opportunity for applying more sophisticated experimental designs and statistical techniques, but, ultimately, it depends on the consensus among medical practitioners, the regulatory agencies, and

the pharmaceutical companies. For the readers who are interested in the position of pharmaceutical industry, they should be referred to "PhRMA Perspective on Population and Individual Bioequivalence."^[24]

Abstract

Pharmacokinetics and pharmacodynamics are divisions of pharmacology that study the action of the body on the drug and the action of the drug on the body, respectively. This entry focuses on population pharmacokinetics and pharmacodynamics modeling a powerful approach in the selection of adequate dosage regimen.

INTRODUCTION

Pharmacokinetics and pharmacodynamics are divisions of pharmacology that study the action of the body on the drug and the action of the drug on the body, respectively. They complete dose titration studies aimed to select rational dosage regimens.

The classical pharmacokinetic (PK)/pharmacodynamic (PD) studies are experimental. They are usually performed on healthy volunteers or highly selected patients to minimize interindividual variability. These studies allow to demonstrate a mechanism and to obtain rough quantitative information on the link between the dose and the effect (PK/PD behavior) of the drug.

Population PK/PD studies quantify the effect of the drug on a population of patients who could use the drug. They allow quantifying, explaining, and predicting how the variability of the drug plasma concentration acts on the variability of the drug effect. They enable optimization (individualization) of dosage regimen. Usually performed on a sample of patients who are representative of the target population, they can be considered as observational studies.

Population PK/PD relies on the use of models. A model can be defined as a simplified description of reality. Most models used in population PK/PD are statistical models. These models describe observations (concentrations and effects), but may also give some outlines of the underlying biological process. This article focuses mainly on the modelling aspects of PK/PD analysis.

First, we recall the definitions of pharmacokinetic, pharmacodynamic, PK/PD, and the population approach. The modelling approach is illustrated with the study of the curious toxic effect of topotecan, an anticancer drug. Simulations are then performed, by using estimates of the population parameters, to propose a dosage regimen with a controlled toxicity.

DEFINITIONS

One of the primary goals of drug development is to generate data that permit to select the appropriate starting dose of the drug and, subsequently, to adjust dosage to the needs of a particular patient or group of patients. Ideally, such knowledge should allow to increase the likelihood of achieving the intended therapeutic effect while reducing the risk of adverse events. One clinical development approach used to achieve this is multidose-level clinical parallel dose–response testing, which is represented in [Fig. 1](#).

However, as advocated by Toutain,^[1] this approach does not allow provision of information on the shape of effect for a particular patient. The different doses are compared with statistical tests; thus the selected doses depend heavily on the minimum difference that can be evidenced with a given power. In this case, a large interindividual variation makes difficult the discrimination between dose effects and is considered as a difficulty in the dose selection.

A PK/PD approach gives a better insight in understanding how the body acts on the dose to give concentrations (PK step) and how variations of these concentrations are involved in the effect (PD step) (cf. [Fig. 2](#)). Holford and Sheiner^[2,3] give more precise definitions of pharmacokinetics, pharmacodynamics, and PK/PD.

Population Pharmacokinetics

Pharmacokinetic models describe the interaction between drug input and the drug disposition. Usual functions used to describe the drug input are intravenous bolus, infusion for a given time, first-order process that approximate the oral absorption.

Compartmental models are the most common approach used to describe drug disposition. Compartments are virtual spaces within which drug distribution is assumed to

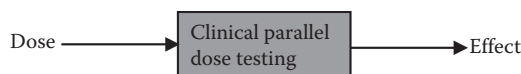

Fig. 1 A clinical design allows to study the effect of doses. It can be considered as a black box. The dose is the input; the effect is the output

be uniform. A compartment is characterized by its apparent volume (which is simply the constant of proportionality between the quantity of drug it contains at a given time and the drug concentration at this time) and clearance parameters (which measure the magnitude of the rates of flow of distribution and elimination). In multicompartment models, the clearances between two compartments are assumed to be equal in both directions.

As an example, in the PK/PD analysis presented hereafter, an anticancer drug (topotecan) was administrated to ($N = 42$) women by 30-min intravenous infusions on five consecutive days. Total topotecan plasma levels were analyzed according to a two-compartment model with linear elimination from the central compartment (cf. Fig. 3). The pharmacokinetic parameters were the clearance (CI) of the central compartment, the volume (V_c) of the central compartment, the volume (V_p) of the peripheral compartment, and the clearance Q between compartments.

The drug concentrations measured in two patients receiving the same dose at the same time after a drug administration are not equal. This variability can be decomposed into two parts: a within-patient variability (essentially explained by analytical error) and a between-patients variability, explained by different pharmacokinetic parameters.

Population pharmacokinetics studies the variability of PK parameters and the variability of concentration profiles. The main idea, which governs population pharmacokinetics, is that each patient is characterized by one's own PK parameters. Making inference on the "population" of PK parameters is then equivalent to making inferences on the population of patients.

Patients involved in population PK studies are representative of a population of patients who intend to use the drug. The "representativeness" is measured with respect to all potential sources of variations of the drug concentrations. As an example, if the concentration profiles observable in males are the same as the ones observable in females, it is not necessary to include both genders in the sample. Using a representative sample makes possible the identification of covariates that explain (or at least are correlated to) the concentration variability. For a given patient, it is then

Fig. 3 A two-compartment model with linear elimination from the central compartment was used to describe the drug kinetics

possible to predict (with the knowledge of its covariates) a typical concentration profile that represents the more probable profile that can be observed on patients with the same value of covariates.

The nonlinear mixed-effects models are usually used to describe these different stages of variability. They can be written as:

$$\begin{cases} C_{ij} = f(\phi_i, t_{ij}) + g(\phi_i, t_{ij}, Y) \varepsilon_{ij}, & j = 1, \dots, n_i \\ \phi_i = A_i \mu + \eta_i, & i = 1, \dots, N \end{cases} \quad (1)$$

where C_{ij} is the concentration measured on the i th patient at time t_{ij} , ϕ_i is the p -vector of individual kinetics parameters for the i th patient, $f(\phi, t)$ is the mean concentration at time t for an individual with a kinetic parameter ϕ , and ε_{ij} are independent $N(0,1)$ random variables. The function $g(\phi, t, \beta)$ is the standard deviation of the error of a concentration measurement at time t . Usually, the different concentrations are assumed to be measured with a constant coefficient of variation β , in other terms $g(\phi, t, \beta) = \beta f(\phi, t)$.

The mean variations between the ϕ_i can be explained by covariates whose values are contained in the columns of the matrices A_i . The independent random variables η_i represent the differences between the actual individual kinetic parameters and their average $A_i \mu$. They are assumed to be distributed according to a $N(0, \Omega)$ distribution. Thus the parameters that have to be estimated are (μ, Ω, β) .

PK/PD

Pharmacodynamics allows to relate the drug effect (PD effect) to the concentration at its site of action; therefore, it is independent of time. The rationale for PD studies is a better understanding of the physiological response to a drug. The choice of PD response is often difficult and is out of the scope of this paper. Most drugs circulate in

Fig. 2 The PK/PD approach splits the black box of clinical trial into two "grey boxes." The first box transforms a dose into a concentration (PK), whereas the second box links the concentration to the effect (PD)

different tissues, but the observation of concentration at the effect site is even difficult or impossible. Actually, the drug concentrations are easily accessible; thus they are measured in plasma. For this reason, modeling mainly focuses on establishing a link between the plasma (or blood) drug concentration and the PD effect. To avoid confusion with pharmacodynamics, Holford and Sheiner suggested to name PK/PD the link between the drug plasma concentration and the PD effect.

Several classes of PK/PD models exist. The simplest ones are direct models in which there is no delay between a change in plasma drug concentration and a change in effects. This occurs when the site of action has reached equilibrium with plasma.

Indirect models allow describing a delay. This delay may be explained by the fact that the concentration is measured in plasma that is not in equilibrium with the site of action. A plot of effects-vs.-plasma concentrations (ordered by time) showing a curve (hysteresis curve) that turns counterclockwise measures the degree of lag between the change in plasma concentration and that at the effect site. A usual way to model this delay is to add an effect compartment to the kinetic model. This compartment, which is linked to the plasma concentration compartment, mimics the site of action of the drug. Because this site has usually negligible volume compared to the volume of the plasma, the PK/PD analysis is performed in two steps. First, the PK models without the effect compartment are used to estimate the PK parameters. Then PD data are analyzed with the PK model with the effect compartment in which the PK parameters obtained in the first step are maintained fixed. In this second step, only the volume of the effect compartment and its rates of exchange with the central compartment of the PK models are estimated.

The last class of PK/PD models is the physiological class. In these models, the effect of the drug is mediated by some indirect mechanism that is located separately from its site of action. The example given below is an illustration of a model of this class. An anticancer drug administered to patients gives toxicity—a decrease of neutrophil cell count. Each dividing cell is likely to be killed when this drug is present. From a macroscopical point of view, the bone marrow produces progenitor stem cells that divide rapidly, and so can be killed. If these cells survive, they continue to mature without obstacle in the bone marrow. Finally, they migrate into the blood—the observed pool—as white blood cells.

In a regulatory point of view, knowledge of PK/PD relationships can contribute to the strength of evidence to support efficacy and to address issues and questions related to the safety of drug doses and dosing regimens in certain populations of patients. The ICH E4 guideline for industry, “Dose–Response Information to Support Drug Registration,”^[4] describes the purpose of exposure–response information and the uses of dose–response and/or concentration–response data in choosing doses during

the drug development process. A recent US Food and Drug Administration (FDA) guidance for industry, “Exposure–Response Relationships: Study Design, Data Analysis, and Regulatory Applications,”^[5] provides recommendations for sponsors and applicants on the use of exposure–response information in the development of drugs by focusing on human studies.

Population PK/PD

If there exists a between-subjects variability in plasma drug concentration, this variability is generally lower than the one observable in effects. This is essentially due to the variety of potential sources of variations of the PD response. Population PK/PD models allow the description of this variability. These models are obtained by adding to the population PK models (Eq. 1) two components describing how the effects vary with concentration (and eventually time) and how the parameters involved in the first component vary between individuals or/and within individuals (interoccasion variability), respectively:

$$\begin{cases} Y_{ij} = N(\psi_i, \phi_i, t_{ij}) + h(\psi_i, \phi_i, t_{ij}, Y) \varepsilon_{ij}, & j = 1, \dots, n_i \\ \psi_i = m + \eta_i, & i = 1, \dots, N \end{cases} \quad (2)$$

where Y_{ij} is the response measured on the i th patient at time t_{ij} , ψ_i is the p -vector of individual PD parameters for the i th patient, $N(\psi, \phi, t)$ is the mean PD response at time t for an individual with a PK parameter ϕ and a PD parameter ψ , and ε_{ij} are independent standard Gaussian random variables. The function $h(\psi, \phi, t, \beta)$ is the standard deviation of the error of a PD response at time t . Usually, the different responses are assumed measured with a constant coefficient of variation β , in other terms $h(\psi, \phi, t, \beta) = \beta N(\psi, \phi, t)$.

As with the PK model, covariates that explain the between-subjects variability can be incorporated within the ψ_i population mean m . The independent random variables η_i represent the differences between the actual individual PD parameters and their average m . They are assumed to be distributed according to a $N(0, D)$ distribution. The parameters that have to be estimated are (m, D, β) . The framework of analysis for standard direct and indirect models is fully developed in Refs. [2] and [3].

Simulations that use estimates of PK and PD population parameters are performed to predict the variability of effects that can be encountered within the whole population with a specific dosage regimen. Such a simulation approach is now used to optimize the design of clinical trials.

Finally, the dosage regimen can be individualized to control the effect on a patient by taking into account the different covariates involved in the explanation of PK/PD variability.

There is no explicit regulatory requirement regarding “population PK/PD,” but the US FDA guidance for industry on population pharmacokinetics^[6] opens the door to widespread application of mixed-effects predictive models and provides guidelines that can be used for population PK/PD analyses.

Software for Population PK/PD Analysis

One of the most commonly used softwares for population PK and PK/PD analysis is NONMEM (the acronym for nonlinear mixed-effects modelling).^[7] NONMEM allows to fit nonlinear mixed-effects (statistical regression-type) models. A powerful feature of mixed-effects modelling is its ability to accommodate patient data as they arise in the course of routine clinical therapy, where data are typically sparse and obtained at unstructured times. The maximum likelihood estimator of the unknown parameters of models (Eqs. 1 and 2) cannot be easily computed in a closed way. The main estimation method used in NONMEM is first order (FO). It consists in approximating the model described by Eq. 1 (Eq. 2, respectively) by performing a first-order Taylor expansion of f and g (N and h , respectively) about the mean value of the random variables ϕ_i (ψ_i , respectively). Thus the obtained models are linear with respect to the random effects, and their parameters can be estimated using standard methods.

AN EXAMPLE

The following study gives an example of the modelization process and it shows conclusions that can be expected from a population PK/PD study. The method and results presented here are fully developed in Ref. [8].

A study was performed to find an admissible regimen, which is effective and controls the toxic effect of topotecan. Topotecan is an anticancer drug given by intravenous infusion to women with ovarian cancer as second-line therapy (cf. Ref. [9], for instance). The major toxic effect of topotecan is a decrease in neutrophil count, which occurs 8–15 days after drug administration (Fig. 4). A primary index used to measure this is the time the neutrophil count remains below the fixed limit: 500 PN/mm³. Another index is the minimum neutrophil count reached. It has been shown in mice^[10] that this toxicity varies not only with the dose given, but also, importantly, with the duration of the exposure to the drug. Thus, when the total dose is given in a single infusion, a low toxicity is observed; but when the same total dose is fractionated over 5 days, toxicity is high. Surprisingly, when it is fractionated over 20 days or more, toxicity is reduced.

The analysis is presented in three sections. “The Pharmacokinetic Model” describes briefly the PK model and gives the population estimates. The analysis of a physiological

Fig. 4 An example of observed and fitted neutrophil profiles. The horizontal line at 0.5×10^3 PN/mm³ allows one to define the primary index of toxicity (time spent below)

(PD) model that explains the toxicity observed in mice and the discussion on the PK/PD link are presented in “The Pharmacodynamic Model.” Then, using this model, the occurrence and magnitude of the toxicity in-patients are predicted using simulations.

The Pharmacokinetic Model

Topotecan was administrated by 30-min intravenous infusions to $N = 42$ women on 5 consecutive days. For each patient, the three first daily doses were fixed a priori, and the two last doses were adjusted to reach a total area under the curve (AUC) within a targeted range (37,500–75,000 nM min). The PK data were analyzed by Friberg et al.^[11] on a subsample of $N_1 = 31$ women. Let us recall briefly their results. Total topotecan plasma levels were analyzed according to a two-compartment model with linear elimination from the central compartment. The resulting individual parameters were the clearance Cl of the central compartment, the volume V_c of the central compartment, the volume V_p of the peripheral compartment, and the clearance Q between compartments. This clearance Q was assumed to be fixed in the population, and estimated by $\hat{Q} = 46.6$ l hr⁻¹. The individual PK parameters $\phi_i = (\ln Cl_i; \ln V_{ci}; \ln V_{pi})$ were assumed to be independent identically distributed (i.i.d.) and drawn from a Gaussian $N(\mu, \Omega)$ distribution, and the covariance matrix Ω was assumed to be diagonal. The estimation of (μ, Ω) obtained from Ref. [11] in the subsample of size 31 is given in Table 1.

Table 1 PK Population Parameter Estimates

	$\ln Cl$	$\ln V_c$	$\ln V_p$
$\hat{\mu}$	2.99	3.66	3.35
$\sqrt{\hat{\Omega}}$	0.42	0.55	0.38

Clearance (Cl) is expressed in liters per hour; volumes V_c and V_p are expressed in liters.

Finally, the individual parameters ϕ_i were predicted by the Bayesian estimates (maximum a posteriori) for all 42 patients. In the rest of this article, the kinetic profiles are considered as known and fixed.

The Pharmacodynamic Model

The discussion concerning the pharmacodynamic model is divided into three parts. First, a physiologically based structural model is chosen. Then, we consider the properties and choice of the function describing the drug action on cells. Finally, a nonlinear mixed-effects model is set up, and its parameters are estimated.

The Choice of the Structural Model

Topotecan is a drug that acts during the replication of DNA. It binds to topoisomerase I when this enzyme is unwinding DNA. At this stage, replication is stopped, DNA is broken, and the cell dies. Thus, each dividing cell is likely to be killed when topotecan is present. From a macroscopical point of view, the bone marrow produces progenitor stem cells that divide rapidly, and so can be killed. If these cells survive, they continue to mature without obstacle in the bone marrow. Finally, they migrate into the blood—the observed pool—as white blood cells. When no drug is given, this system is at equilibrium, and can be described using the family of compartmental models given in Fig. 5.

Bone marrow constitutes a nonobserved part of the life of these cells. To get information about this part, a large number of different outputs (neutrophil profiles), obtained with a large number of different inputs (kinetics), are necessary. We have at our disposal roughly a single shape of PK profile. Remember that all the women received five consecutive daily infusions, and that the two last doses were adjusted so as to reach a target AUC. Consequently, the data are not rich enough to allow a precise description of the actual model. Therefore, we deliberately chose to use a model built on numerous data for 5-fluorouracil in rats.^[12] As this drug acts at the same stage as topotecan, it appears reasonable to take the structure of the rat model and to scale it to humans, although we will see that slight modifications are necessary. The model used in Ref. [12] contains five compartments.

Two compartments are sensitive to the drug, two are nonsensitive, and the last compartment is the blood pool. The exchanges are second-order exchanges, except for what leaves the blood, which is of order 1. All bone marrow compartments share the same second-order constant k . Recall that when the exchanges are of order 2, the behavior of a given cell depends on the size of the compartment. The more cells present in this compartment, the more rapidly this particular cell will move. This type of exchange roughly mimics the birth of new cells in the compartment, and describes adequately the observed neutrophil profiles, which quickly leave and come back to baseline. In the original model,^[12] the production rate was assumed to be constant, up to a feedback mechanism. More precisely, if N_{base} is the baseline neutrophil count, and $N(t)$ is the neutrophil count at time t , then the production rate is set to $k_{\text{in}} N_{\text{base}}/N(t)$. Finally, the action of the drug is modeled by a first-order killing rate on each of the two sensitive compartments. This killing rate is assumed to be linked directly to the drug concentration C_t at time t : $F(C_t) = k_e C_t$.

Applying this model to data on women, the individual curve fitting was not satisfactory, for two reasons. The feedback leads to a rebound, which is pronounced in rats. As it is missing in human patients, this feedback mechanism is inappropriate for our study. Without feedback, the model used in Ref. [12] appears to be too constrained to allow a rapid decrease or increase of the curve. In this model, cells have to spend the same time in the two different states (sensitive/nonsensitive). For this reason, we chose two different rates of exchange (k and k'), as shown in Fig. 5. The mean residence time of a cell in the nonsensitive region is then approximately proportional to the number of nonsensitive compartments, $2k'^{-1}$. Similarly, the mean residence time of a cell in the sensitive region is proportional to $2k^{-1}$. In other respects, we notice that increasing the number of nonsensitive compartments does not determine another dynamic behavior because an increase in k' can compensate. The same argument applies to the number of sensitive compartments and the constant k .

In summary, there are two differences between the previous model in Ref. [12] and ours: feedback is discarded and two rates of exchange are used instead of one. The differential equations driving the selected model are now detailed.

Fig. 5 General compartment model. The first four compartments are the different stages of a cell life in the bone marrow. The last compartment is the blood pool. In the original model, it was assumed that $k = k'$ and that a feedback mechanism (a link between compartments 5 and 1) was used

The neutrophil profile in the blood is the solution $N(t)$, $t \geq 0$, of the system:

$$\begin{cases} \frac{\partial X_1}{\partial t} = k_{in} - kX_1^2 - F(c_i)X_1 \\ \frac{\partial X_2}{\partial t} = kX_1^2 - kX_2^2 - F(c_i)X_2 \\ \frac{\partial X_3}{\partial t} = kX_2^2 - k'X_3^2 \\ \frac{\partial X_4}{\partial t} = k'X_3^2 - k'X_4^2 \\ \frac{\partial N}{\partial t} = k'X_4^2 - k_{out}N \end{cases} \quad (3)$$

When $t = 0$, the system is at equilibrium, i.e., $X_1(0) = X_2(0) = \sqrt{k_{in}/k}$, $X_3(0) = X_4(0) = \sqrt{k_{in}/k'}$, and $N(0) = k_{in}/k_{out}$. In the following, the neutrophil profile denoted by $N(t)$ is also denoted by $N(F)(t)$ to emphasize the dependence on F . In the final model, $F(C_i)$ is set to $k_e C_i$. “Drug Action: The PK/PD Link” deals with the rationale of this choice.

Drug Action: The PK/PD Link

The choice of the drug action, modeled by the killing function F , has not yet been discussed. The killing function $F(c)$ has some obvious properties: It cancels at $c = 0$ (no drug, no action), and it is increasing (more drug, greater effect). Intuitively, the shape of F determines the drug action: when F is convex, low concentrations give little toxicity; but when F is concave, low concentrations rapidly give toxicity. Consequently, for a fixed total dose, it seems that when F is convex, a low target toxicity can be reached with a large number of small doses; whereas when F is concave, the same target toxicity will be reached with a small number of high doses. Thus the shape of F seems to be of major importance, especially in the context of this paper.

Actually, the impact of the shape of F is reduced by the existence of a limit of toxicity. This limit is intrinsic to this family of catenary models. It is reached when the sensitive compartments are emptied (by the drug action). In that case, whatever the killing rate, the drug cannot kill more cells than those arriving in these compartments. Even if the killing rate $F(C_i)$ is very high, its effect on the system is very similar to the one that would be obtained with a smaller killing rate. Two different mechanisms drive the toxicity: when $F(C_i)$ is low (below the limit of toxicity), the shape of F determines the toxicity; when $F(C_i)$ is high, only the time it spends above the limit of toxicity governs the effect. These intuitive considerations need to be formalized to quantify the maximal effects.

To this end, let Δ be a fixed length of time and $0 < \varepsilon < 1$.

Let $T = 1/\sqrt{k_{in}/k}$ ($T' = 1/\sqrt{k_{in}/k'}$, respectively) be the mean residence time in the sensitive compartments (nonsensitive compartments, respectively) at steady state. Let $N_b = k_{in}/k_{out}$ be the neutrophil count at steady state (neutrophil count at baseline). Set:

$$K_0 = \max \left\{ \frac{1}{\Delta} \ln \left(\frac{20}{\varepsilon} \sqrt{\frac{k'}{k}} \right); \frac{4}{3\varepsilon \min\{T, T'\}} \left(6 + 4 \frac{\Delta}{T'} \right) \right\} \quad (4)$$

For all killing rate functions $F(C_i)$, the following property is true: if $F(C_i) \geq K_0$ on an interval of length Δ , say $[t_0, t_0 + \Delta]$, then decreasing F to K_0 on the interval $[t_0, t_0 + \Delta]$ does not change the effect more than εN_b .

More precisely: $\sup |N(F)(t) - N(F^{(K_0)})(t)| \leq \varepsilon N_b$, where $F^{(K_0)} = F$ outside $[t_0, t_0 + \Delta]$ and $F^{(K_0)} = K_0$ on $[t_0, t_0 + \Delta]$.

The proof of this result is deliberately omitted because it is too long and without practical interest. Notice that K_0 , as previously defined, does not depend on F . The main consequence of this property is that all shapes of F above K_0 give nearly the same toxicity. A simple way to explain this property is to consider the following example. Let us take the first patient of this study. Assume that her kinetics $(C_i)_{i \geq 0}$, as well as her structural parameters (k_{in}, k, k', k_{out}) are known. Assume now that the killing function F is a step function: $F^{(K)}(c) = 0$ if $c < c_0$, $F^{(K)}(c) = K$ elsewhere, and c_0 is known. Because $(C_i)_{i \geq 0}$ and c_0 are fixed, the lapse of time Δ during which $C_i \geq c_0$ is fixed (e.g., $\Delta = 5 \times 1$ hr). The proposition says that for all $\varepsilon < 1$, there exists K_0 such that for all $K \geq K_0$, $\|N(F^{(K)}) - N(F^{(\infty)})\|_\infty \leq \varepsilon N_b$.

This last inequality means, first, that toxicity is limited by the one given by $N(F^{(\infty)})$. Second, it implies that when K becomes large, the shape of the neutrophil curve becomes constant.

A first consequence of this property is an estimability problem of F . Even if the map $K \rightarrow N(F^{(K)})$ remains injective, its derivative tends to zero (uniformly on time) when K is large. Thus, if the actual K of the considered individual is large (more than K_0), the Fisher information matrix is nearly degenerate, which implies that the maximum likelihood estimator of such a K has too a large variance to be useful in practice.

Whatever is the shape of F above K_0 , it cannot be properly estimated with a reasonable variance. Thus whatever is the chosen parameterization for F , there exists an area of this parameter space where the estimation is difficult. The estimation quality (variance of the estimator) of the parameters governing the shape of F below K_0 depends on the quantity of information available below this limit. If this information is poor, a large variance of the estimator is expected whatever is the parameterization of F . In such a case, the simplest shape for F is to be preferred (i.e., a linear shape). As already mentioned, all women of the study have very similar kinetic profiles, so that the information of the data only concerns a narrow range of concentrations.

Thus we are confronted with two possibilities: either the drug concentrations lead to killing rates above K_0 , thus we have no information about the shape of F for small concentrations, or the drug concentrations lead to small killing rates; but because the range of these concentrations is narrow, the shape of F can be documented for only a small interval of concentrations. In both cases, the linear killing rate $F(c) = k_c c$ has to be chosen.

The second consequence drawn from this property is a qualitative explanation of the toxic behavior observed in mice.^[10] Recall that with a single dose, the observed toxicity is low: because concentrations reach high values, they lead to high killing rates (above K_0), but only for a short time. When this dose is fractionated over 5 days, concentrations are lower but are high enough to lead to killing rates above K_0 . Because the total time spent by the killing rate above K_0 is long, toxicity is high. Finally, when the total dose is fractionated over 20 days, concentrations are too low to give high killing rates and high toxicity. Thus, our model implies a high correlation between toxicity and the time spent by the killing rate above K_0 . That is exactly what is observed in Ref. [10]: a high correlation between toxicity and the time the drug concentration remains above 0.7 μM .

The Population PK/PD Analysis

As it can be seen on a patient-by-patient analysis, both the response curves and the individual PD parameter $\psi = (\ln k_{in}, \ln k, \ln k', \ln k_e)$ vary widely. The PD analysis relies on the concentration time course. Recall that the individual PK profiles are known. We assume here, as have others,^[12,13] that k_{out} does not vary among patients and is equal to $\sim 0.1 \text{ hr}^{-1}$.

The family of nonlinear mixed-effects PD models described by Eq. 2 has been used with $h(\psi_i, \phi, t_{ij}, \sigma) = \sigma N(\psi_i, \phi, t_{ij})$ and $N(\psi, \phi, t)$, with the neutrophil count defined by Eq. 3. For each patient, the neutrophil count $N(\psi_i, \phi_i, t_{ij})$ depends on the PK parameter (ϕ_i). The ψ_i are assumed to be independent of the PK individual parameters ϕ_i . Because all the parameters (k_{in}, k, k', k_e) are positive, we parameterized the model with their logarithm and assumed these logarithms to be distributed according to a normal distribution with mean m and variance D .

With regard to the number of patients involved in the trial, we chose to take D as a diagonal matrix. The estimation method used is FOCE;^[7] it provides an asymptotically Gaussian estimator $\hat{\theta} = (\hat{\sigma}^2, \hat{m}, \hat{D})$ of θ whose asymptotic variance will be denoted by $V(\theta)$.

Table 2 gives the estimation of σ^2 , m , and $\sqrt{D}$, as well as their asymptotic standard error (in parentheses).

It turns out that the optimized criterion (FOCE) has a large number of local minima, reflecting a large distance from the asymptotic framework. Therefore the asymptotic variance-covariance matrix of the estimator should be interpreted with care.

An example of an individual fitted curve is given in Fig. 4.

Table 2 PD Population Parameter Estimates

	$\ln k_{in}$	$\ln k$	$\ln k'$	$\ln k_e$
m	-1.02 (7.4×10^{-3})	-10.1 (0.14)	-7.92 (0.30)	1.55 (0.076)
$\sqrt{D}$	0.39 (0.98)	2.07 (0.82)	0.62 (0.23)	0.84 (0.37)
σ^2	0.37 (0.17)			

Simulations and Toxicity Predictions

This section is devoted to giving a whole set of dosage regimens with controlled toxicity. Recall that the primary measure of toxicity is the time spent with the neutrophil counts below 500 PN/mm^3 . When this time is longer than 7 days, toxicity is considered intolerable. First, we give an index that allows one to decide qualitatively whether, for a given regimen, the toxic behavior of the drug is rather concentration-dependent (toxicity is linked to the daily dose) or time-dependent (toxicity is linked to the time spent by the drug concentration above a limit). Finally, we give quantitative results that determine set dosage regimens with acceptable toxicity.

Simulation of a PK Toxicity Index

The limit of toxicity K_0 gives information on exposure to the drug. It can be used as a surrogate that gives some useful complementary information on the toxic behavior. Indeed, as previously seen, when drug concentrations are low, the drug toxicity is concentration-dependent. But as soon as the limit K_0 is reached, toxicity depends on the time spent above K_0 and is rather time-dependent.

Let us define a toxicity index (TI). For a chosen duration Δ and a chosen $\varepsilon > 0$ (these choices are discussed later), we set $\text{TI} = K_0/k_e$. The main advantage of this index is that it is homogeneous to a drug plasma concentration and can be compared directly to the kinetic profile. Because both K_0 and k_e vary among patients, it is possible to simulate their distribution and then to derive the 5% percentile of TI. In other respects, as has been shown,^[14] it is possible to use covariates such as creatinine clearance to predict for each patient the PK profile for a dosage regimen chosen a priori. As an example, assume that the expected concentration remains below the 5% quantile of TI. It means that the early sensitive compartments are not emptied by the action of the drug, with a probability of 95%. This implies that the toxicity is concentration-dependent with this dosage regimen. It would not be so if the concentration time course had crossed the index TI for longer than Δ .

Let us detail the rationale for the choice of ε and Δ . As can be seen on Eq. 4, K_0 depends on maturation times T and T' , whose values are about 260 and 90 hr. Therefore, K_0 is about $(120\varepsilon)^{-1}(6 + 0.044\Delta)$. Moreover, it is natural to set Δ below 24 hr—the delay between two consecutive

infusions. So the influence of the term 0.044Δ is low compared to 6. We set $\Delta = 5$ hr. It remains to choose ε , which is a proportion of the baseline neutrophil count. If the difference between two neutrophil profiles is of the same order as the critical threshold, then the resulting toxicities are similar. Recall that the critical threshold (500 PN/mm^3) is around 10 times less than the baseline neutrophil count. These considerations lead us to choose $\varepsilon = 0.05$ (5%). Even if this rough method does not tell us directly whether or not an intolerable toxicity is reached, it gives qualitative information about the toxic behavior.

Simulation of Admissible Dosage Regimens

The aim of this part is to predict the set of admissible dosage regimen. A dosage regimen is said to be admissible if an intolerable toxicity occurs for less than a fixed percentage of patients (say 5%). We limited ourselves to dosage regimens with constant daily doses (one infusion each day) and proceeded as follows. For a fixed dosage regimen (i.e., with a fixed number of infusions and a fixed daily dose), we determined the percentage of patients with intolerable toxicity by using a simulation method detailed hereafter. Then, the dosage regimen was adjusted to obtain a percentage equal to 5%. Now, let us detail the simulation method. First, a sample $\theta_j^* = (\sigma_j^{*2}, m_j^*, D_j^*)$ of size 200 was drawn from a $N(\hat{\theta}, V(\hat{\theta}))$. Next, for each θ_j^* , two samples $(\psi_{ij}^*)_{i=1,\dots,150}$ and $(\phi_{ij}^*)_{i=1,\dots,150}$ were drawn from $N(m_j^*, D_j^*)$ and from the PK population distribution $N(\hat{\mu}, \hat{\Omega})$, respectively, given in section devoted to “Population Pharmacokinetics.”

Then, $Y_{ij}^*(t) = N^*(\psi_{ij}^*, \phi_{ij}^*, t)$ was computed, as well as the time $T_{ij}^* = \int_0^\infty 1_{Y_{ij}^*(t) \leq 500 \text{ PN/mm}^3} dt$. The proportion of patients with intolerable toxicity was then estimated as the percentage $\frac{1}{200 \times 150} \sum_{ij} 1_{T_{ij}^* \leq 7 \text{ days}}$.

Fig. 6 gives the critical daily dose obtained with these simulations as a function of the number of infusions. This figure shows that the toxicity occurrence increases with the total dose. Moreover, total doses that give few toxicities do not depend on the number of infusions: it is about 0.17 mg for 5% toxicity and about 1.22 mg for 10% toxicity. In other words, if the target total dose is low, the number of infusions can be chosen as desired without any change of the toxicity occurrence. A striking fact shown in this figure is that the total admissible dose giving 30% toxicity decreases from 6.2 mg (for one infusion) to 4.9 mg (for 15 infusions), and then it increases up to 5.1 mg for 21 infusions. Because 6.2 mg for one infusion produces the same toxic effect as 4.9 mg for 15 infusions, the 1-day schedule can be considered as less toxic than the 15-day schedule (it takes more drug to produce this level of toxicity). Similarly, the 21-day schedule appears to be less toxic than the 15-day schedule. These assertions have been clinically evidenced (cf. Ref. [15] for instance). Fig. 6 is a tool for comparing schedules in a rather qualitative way.

Fig. 6 Curves giving the set of dosage regimen with the same fixed occurrence of toxicity (5%, 10%, and 30%). (View this art in color at <http://www.dekker.com>.)

Fig. 7 Cumulative distribution function of intolerable toxicity for the 1-day, 5-day, and 21-day schedules

Figure 7 gives the full quantitative description of toxic effects for these schedules: 1, 5, and 21 infusions.

Notice that the three curves are superposed for low doses/low toxicities. This means that when the total dose is low, the occurrence of toxicity does not depend on the number of infusions, illustrating the concentration dependence and toxic behavior of the drug. When the total dose increases, the occurrence of toxicity tends to plateau at a level that depends on the number of infusions, and below 100%. This is a consequence of the phenomenon described in “Drug Action: The PK/PD Link.” When the limit of toxicity K_0 is reached (with high concentrations), the drug toxic behavior becomes time-dependent. Of course, this study deals only with neutropenia, and many other types of toxicity may occur with high drug doses.

Recall that five infusions were administered and the daily dose could vary during the cycle. The total dose varied between 4.77 and 14.3 mg. As the total dose was

not equally fractionated on the 5 days, we chose to simulate the percentage of intolerable toxicity in our sample as follows. For the i th patient, a sample $(\psi_{ij}^*)_{j=1,\dots,100}$ was drawn from the PD population distribution $N(\hat{m}, \hat{D})$. These 100 individuals were given the PK parameters of the i th patient, as well as her five daily doses. The critical times $T_{ij}^* = \int_0^\infty 1_{N(\psi_{ij}^*, \hat{\sigma}_{ij}^*, t) \leq 500 \text{ PN/mm}^3} dt$ were computed. The proportion of intolerable toxicity in the sample was then estimated as the percentage $\frac{1}{42 \times 100} \sum_{ij} 1_{T_{ij}^* \leq 7 \text{ days}}$. We obtained 39%.

To see if this prediction agrees with the data, the empirical percentage of toxicity in the sample was evaluated by interpolating linearly the observed neutrophil counts for each woman. With this method, only seven women (17%) showed an intolerable toxicity, which is far from 39%. Actually, the empirical percentage of toxicity depends on the chosen method of interpolation. As the neutrophil profiles are convex around their minimum, the linear interpolation underestimates the time spent below 500 PN/mm³, especially when certain observation times are far from each other. With a smooth interpolation, 19 women (45%) showed an intolerable toxicity, which is in agreement with the predicted percentage of toxicity.

CONCLUSION

Population PK/PD modeling provides a powerful approach in the selection of adequate dosage regimen. Even if the modelization given in this paper is only the first step of a longer modelization process (range of concentrations are too narrow to allow estimation of F ; efficacy is not studied), it shows the richness of conclusions that can be reached: the control of the effects (toxicity, efficacy, and so on) via a rational choice of individualized dosage regimen. This example also evidences the weakness of this approach.

The main impediment to the systematic implementation of this approach is the lack of methods to validate the model. Actually, the choice of a specific PK/PD model lies on a number of assumptions that are not easy to check: representativeness of the sample, normality of random effects, assumptions on the structure of variance, and so on. These assumptions have an influence on the predictions that can be drawn from a specific study (especially those obtained by simulations). Also, even when the adopted model provides a good fitting, there is no guarantee that the obtained predictions can be trusted. General statistical methods, such as tests on the variance components, would be extremely useful in the rational choice of model.

Semiparametric (nonparametric, respectively) models are probably a partial answer to some of these limitations. In these models, the distribution of the individual effects (the intraindividual random variable, respectively) is estimated. However, the properties of this family of models (at least the asymptotic ones) are not known. More work is needed in this direction.

Postmarketing Adverse Drug Event Signaling

Yi Tsong

U.S. Food and Drug Administration, Rockville, Maryland, U.S.A.

Abstract

Postmarket adverse drug reaction (ADR) surveillance is designed exactly for the purpose of identifying the low-frequency reactions that are not caught in pre-marketing studies, the high-risk group, drug–drug interaction, the longterm effect of the drug, and the increased severity and/or frequency of known reactions. This entry provides statistical analysis methods for identifying these reactions in a drug.

INTRODUCTION

A sponsor seeking to market a new drug product is required by law to have an application [new drug application (NDA)] reviewed and approved by the U.S. Food and Drug Administration (FDA). The principal requirement of the NDA is that the safety and efficacy of the drug is supported by data collected through phase I to III trials. Often, the clinical trial is composed of relatively healthy patients, with a short study duration for adverse event (AE). Once the drug is marketed, the same drug product is available to a patient population that is broader and not well studied. The drug may be used for indications of different disease states; for longer duration; patients, such as the elderly, children, and women not studied in pre-marketing studies; and in patients exposed also to other treatments, etc. Postmarket adverse drug reaction (ADR) surveillance is designed exactly for the purpose of identifying the low-frequency reactions that are not caught in pre-marketing studies, the high-risk group, drug–drug interaction, the long-term effect of the drug, and the increased severity and/or frequency of known reactions.

OVERVIEW

The FDA started the Spontaneous Reporting System (SRS) in 1968 by collecting, processing, and analyzing adverse drug event (ADE) reports. Most of them were reported on the ADE reporting form designed by the FDA (Form 3500, which was later replaced by the MedWatch Form in 1992) and submitted by manufacturers of prescription drugs as a condition for marketing in the United States,

while others are submitted voluntarily by concerned health professionals and consumers. Each report contains the patient's demographic information including age and gender; AE information, including date and outcome of event; description of event, evidence, and existing medical history; information of suspect and concomitant medicine(s), including drug name, dose and frequency, diagnosis for use, whether the event abated after drug use was stopped, and whether the event reappeared after the drug was reintroduced; and the reporter's name and address. Each report was reviewed by a trained professional in the FDA to assure that the form was complete and the information was correct before it was entered into the computer database. Together, these reports in the FDA database make up the SRS of the United States. Details of the laws and regulations on postmarketing reporting of adverse reactions have been described by Faich,^[1] Anello,^[2] and others.^[3–5] The methods for managing the SRS have also been previously described by Anello.^[6]

In 1997, the FDA overhauled the postmarket Adverse Reaction Reporting System in order to accommodate electronic submission and unify the coding with MedDRA^[7] (a dictionary of adverse drug reactions) and renamed the system to Adverse Event Reporting System (AERS). In comparison to SRS, the post-1996 AERS is more structured, has more capacity, and uses more detailed coding terminologies. The FDA now receives over 200,000 ADE reports annually and currently has over 1.6 million reports in its computerized database. It forms a major database for postmarketing adverse drug event monitoring and screening.

The information in the AERS database is rich but cannot be used for computation of incidence rates of specific AE and drug combinations. The difficulties result from the following three reasons:

1. The method of ascertainment of an AE is not uniform among the reporters and nonreporters, and the reporters have their own criteria for identifying an

The views expressed in this entry are those of the author and do not necessarily represent the official position of the U.S. Food and Drug Administration.

AE. It is generally believed that the number of reports is much smaller than the actual number of events.

2. Although all the reports were reviewed carefully in the FDA, the quality of the information collected for a particular AE varies with the reporter.
3. The population at risk is unknown, hence the number of reports is not necessarily closely related to the number of individuals taking the drug.

In spite of these limitations, AERS is a valuable database that can be used for signaling the possibility of excessive or outlying ADE and for generating hypotheses.

Epidemiological and statistical applications were often used in the signaling process. The ADE signaling procedures used in the United States have evolved in the last three decades. Several statistical approaches have been proposed to evaluate adverse experiences using the SRS database. For example, Knapp et al.^[8] and O'Neill and Harris^[9] investigated screening methods for identifying drugs with excessive rates of adverse experiences on a periodic basis. Norwood and Sampson^[10] and Tsong^[11] investigated statistical procedures for detecting increases in frequencies of adverse experience reporting. Lao et al.^[12] investigated statistical procedures for continuous monitoring of increased reports of adverse experience. Rossi et al.,^[13] Hsu,^[14] and Tsong^[15] studied the procedure to adjust for influential factors when comparing the AE reporting of drugs of the same category. Lately, data-mining techniques have been introduced into this field by DuMouchel^[16] and have received much attention from the FDA^[17–19] and the drug-safety research community. In the following sections, three types of signaling procedures are described and discussed.

MONITORING THE INCREASE OF REPORTING OF ADVERSE DRUG EVENTS

Prior to 1994, reporting of increased frequency of ADE reports of the drug product was part of the regulatory requirement of drug sponsor for the purpose of postmarketing safety monitoring. Reasons for increased frequency can be attributed to increased off-label usage, government policy changes, awareness of the AE, or publicity of reports on the AE. In addition, the sponsors' overeagerness to comply with the policy made the task of assessing the association of the increased reporting with safety concerns beyond manageable. Although the regulatory requirement was waived in 1995, the procedures are still used to signal unusual happenings in ADE reporting. The statistical methods used to detect a significant increase have evolved since the first FDA Draft Guidance for Reporting Adverse Drug Reaction issued in 1985^[4] until the last revision issued in 1990.^[5] The 1985 draft guidance recommended a type I error rate inflated normal approximation estimation method. In 1988, Norwood and Sampson^[10] proposed

a conservative exact method to control the type I error rate. In 1990, an FDA draft guidance^[4] recommended a normal approximation testing method based on a research report published later in 1992 by Tsong.^[11] Tsong^[11] compared the type I error rates of seven methods and concluded that the 1990 FDA draft guidance had the best control of the type I error rate.

Let

X_r, X_c = The random variables of the number of reported ADRs in the reporting interval and referenced interval, respectively;

x_r, x_c = The observed number of reported ADRs in the reporting interval and referenced interval, respectively;

$x_t = x_r + x_c$ = The total observed number of ADRs reported in the two intervals combined;

s_r, s_c = The estimated sales volume in the reporting interval and the referenced interval, respectively;

$s_t = s_r + s_c$ = The estimated sales volume of the two intervals combined;

R = Ratio of sales, s_r/s_c ;

PR = Proportion of estimated sales volume in the reporting interval, s_r/s_t ;

D_r, D_c = The reporting rates in the reporting interval and comparison interval, respectively, i.e., $D_r = E(X_r/s_r)$, $D_c = E(X_c/s_c)$.

The notation can be presented in a two-by-two table in Table 1. Note that x_r, s_r, s_c , and s_t are all known margins.

If there is no increase in the reporting period, then $E(X_r/x_r) = s_r/s_t$. Under such null hypothesis, the number of reports that received X_r in the reporting period would follow the following binomial distribution

$$X_r \sim \text{Bin}(x_t, p), \text{ where } p = s_r/s_t$$

In other words, testing for increased frequency means testing the following hypotheses

$$H_0 : E(X_r) = x_t p \text{ vs. } H_a : E(X_r) > x_t p$$

Under the null hypothesis, the 90% approximate confidence interval of $E(X_r)$ is

$$(Rx_c - Z_{0.95}\sqrt{(x_r + x_c)R}, Rx_c + Z_{0.95}\sqrt{(x_r + x_c)R})$$

where $R = s_r/s_c$. Let

$$C = Rx_c + Z_{0.95}\sqrt{(x_r + x_c)R}$$

A significant increase is concluded if $x_r \geq C$.

^aRxs: in 1000 prescriptions.

As an example, we consider the data presented to the 1992 CDER Advisory Committee on Neuropharmaceutical Drug Products (Table 2). In order to test whether there was an increased reporting of amnesia associated with triazolam after a concern about this ADE was publicized in 1987. The ADE reports and estimated usages of triazolam are divided into two periods (prior to 1987 and in and after 1987) as shown in Table 3.

$$\begin{aligned}
 R &= (\text{Estimated Use in Post-1987 Interval}) / \\
 &\quad (\text{Estimated Use in Pre-1987 Interval}) \\
 &= 33,614 / 32,933 = 1.021 \\
 C &= Rx_c + Z_{0.95} \sqrt{(x_r + x_c)R} \\
 &= 1.021 \times 174 + 1.645 \sqrt{(356 \times 1.021)} = 209
 \end{aligned}$$

As $x_r = 182 < 209$, it was concluded that there was no evidence of significant increase in the frequency of reports after the publicity.

Note that the estimated usage used in these data is the usage projected to the U.S. population. Variation of the estimate is not accounted for in the analysis. In fact, the analysis relies only on the precision of the sales ratio.

SIGNALING OF HIGH REPORTING RATE

Comparing AE reporting using the SRS database often involves two drugs marketed in different years, which presents a unique problem because of the characteristics of the system. The factors that may lead to bias in the comparison include differences in the number of years on the market of the drugs for the years to be compared, differences in manufacturer reporting patterns, differences in

Table 3 Publicity Effect on ADE Report of Amnesia for Triazolam Prior to Publicity—1983 to 1987, Post Publicity—1988 to 1991

Reporting rates	182/33,614	174/32,933
	= 541.4/100,000	= 528.3/100,000

From the 1992 CDER Memorandum for Advisory Committee on Neuropharmaceutical Drug Products.

exposure populations, secular reporting trends, reporting variations, diagnosis and prescription variation, and publicity of the AEs.^[13] Rossi et al.^[13] and Hsu^[14] compared the reports of ADEs associated with piroxicam with seven other NSAIDs that entered the market in different years. They proposed to adjust the number of reports for the market share, differences in reporting patterns associated with the year of marketing, and secular trends of reporting of all ADEs of all drugs combined. They found that the adjusted number of ADE reports for piroxicam ranked first among all NSAIDs. Hsu^[14] also proposed a normal approximation for the confidence interval of the adjusted reporting rates (number of reports per 100,000 prescriptions). Tsong^[15] proposed the application of incidence density statistics to analyze the data.

Using a notation similar to that in the last section, for a given ADE, let x_{1j} , x_{2j} , and $x_j (=x_{1j}+x_{2j})$ denote the number of reports for drug 1, drug 2, and both drugs combined; let s_{1j} , s_{2j} , and s_j denote the number of prescriptions for drug 1, drug 2, and both drugs combined, respectively, in year j ; let R_{1j} , R_{2j} denote the ADE reporting rates for drug 1 and drug 2, respectively, in year j (calendar year). R_{1j} and R_{2j} are estimated by $r_{1j}=x_{1j}/s_{1j}$, $r_{2j}=x_{2j}/s_{2j}$. $RR_j=R_{1j}/R_{2j}$ is the ratio of the two drugs. $P_{ij}=s_{ij}/s_j$ is the proportion of prescriptions for drug i ($i=1,2$) out of s_j , the total prescriptions for drug 1 and drug 2 combined.

Assuming that x_j and P_{ij} are given, under the null hypothesis of equal reporting rates for drug 1 and drug 2, X_{1j} , the random variable of the number of reports for drug 1 (and x_{1j} is the realization of X_{1j}) can be assumed to be distributed as $\text{Bin}(x_j, P_{1j})$ as stated in the last session. For testing $H_0: RR_j=1$ vs. $H_a: RR_j>1$, the binomial test is the conditionally most powerful test. When x_j or x_{1j} is small, the exact binomial p values can be determined. Otherwise, the normal approximation of the binomial test is the following Z test by comparing

$$Z = [x_{1j} - (x_j P_{1j})] / \left[\sqrt{x_j P_{1j} (1 - P_{1j})} \right]$$

against $Z_{\alpha/2}$, where $Z_{\alpha/2}$ is the $(1-\alpha/2)$ th percentile of the standard normal distribution; typically, $\alpha=0.05$. RR_j is estimated by $rr_j=(x_{1j}/s_{1j})/(x_{2j}/s_{2j})$ and its confidence interval can be calculated using Cornfield's method.^[15] The confidence

interval given below based on the simple normal approximation is close to Cornfield's method for the ratio of reporting rates for single marketing year data and pooled data in general without involving complicated computation.

Let $p(x_{ij}) = x_{ij}/x_j$; then, $p(x_{ij})$ is an unbiased estimate of $P(X_{ij})$, the proportion of reports for drug 1; then, the 95% confidence limits of $P(X_{ij})$, p_{Lj} and p_{Uj} , are

$$p_{Lj} = \left\{ x_{ij} + Z_{\alpha/2}^2 - \sqrt{x_j Z_{\alpha/2}^2 [p(x_{ij}) - p(x_{ij})^2] + Z_{\alpha/2}^4 / 4} \right\} / (x_j + Z_{\alpha/2}^2) \quad (1)$$

and

$$p_{Uj} = \left\{ x_{ij} + Z_{\alpha/2}^2 + \sqrt{x_j Z_{\alpha/2}^2 [p(x_{ij}) - p(x_{ij})^2] + Z_{\alpha/2}^4 / 4} \right\} / (x_j + Z_{\alpha/2}^2) \quad (2)$$

Hence the 95% confidence interval for RR_j , the ratio of reporting rates in year j , is

$$((p_{Lj}/P_j)/(q_{Lj}/Q_j), (p_{Uj}/P_j)/(q_{Uj}/Q_j)) \quad (3)$$

where $q_{Lj} = 1 - p_{Lj}$, $q_{Uj} = 1 - p_{Uj}$, $Q_j = 1 - P_j$.

In order to summarize the yearly comparisons, the following Mantel-Haenszel-type statistic is used.

$$Z^* = \frac{\sum_j (x_{ij} - x_j P_j)}{\sqrt{\sum_j x_j P_j (1 - P_j)}} \quad (4)$$

Z^* is approximately distributed as $N(0,1)$ under the null hypothesis of equal reporting rates. R , the overall ratio of rates, is estimated by

$$\sum_j [x_{ij}(1 - P_j)] / \sum_j (x_{2j} P_j) \quad (5)$$

Confidence limits are estimated using Cornfield's method.^[20]

Table 4 presents the amnesia reporting rate per 100,000 prescriptions of triazolam and temazepam, the ratio of reporting rates, and the corresponding 95% confidence limits for each calendar year when either one of the drugs was in the market, as well as the statistics for all years pooled and summarized. The data were presented in the 1992 CDER Memorandum for Advisory Committee Meeting on Neuropharmaceutical Drug Products.

When comparing the reporting rates of two drugs first marketed in different years, one needs to consider the year factor that may bias the comparison in the following two ways. Due to the well-established evidence that the first three years of marketing result in many more ADE reports than later years (Fig. 1),^[22] regardless of the actual incidence of such reactions, one may need to stratify the data by marketing year in order to adjust for this effect (Table 5). However, once the data are stratified by the marketing year, one has to compare the reporting rates that occurred in different calendar years. The U.S. reporting of all ADEs of all drugs combined is not at a constant rate through all the years. There is a large variation in the reporting rates during the 1968 to 1994 interval (Fig. 2). Although it is difficult to explain this fully, part of the

^aRxs: in 1000 prescriptions.

^bRate: number of reports per 100,000 prescriptions.

^cRatio of reporting rates = (rate of triazolam reports)/(rate of temazepam reports).

*Excluding 1981 and 1982 when there was no usage of triazolam.

Fig. 1 Amnesia reporting rates of triazolam, temazepam, and all-drug-all-event reporting rate

decrease in all-drug-all-ADE reporting rates from 1968 to 1980 was due to the changes in policy on what to report, while the increase observed after 1980 was partially due to the promotion of the reporting system, the increased effort of the manufacturers, and the availability of more medicines. However, this increase in reports appears to be independent of manufacturer.

The trend with time changes of reports of all ADEs of all drugs combined can be fitted rather well with a quadratic regression curve for its good fit and simplicity. The data are best described with the quadratic regression curve

$$\text{Rate} = 10.96 + 1.34(\text{year} - 1981) + 0.11(\text{year} - 1981)^2$$

The expected all-drug-all-ADE reporting rates for each year are given in Table 5. In comparing the amnesia ADE reporting rates of triazolam and temazepam in their marketing years, one must need to adjust the ratio of rates according to the differences resulting from the secular trend of reporting of all ADEs of all drugs combined of the two calendar years in comparison. For example, in 1983, the first marketing year of triazolam, the reporting rate of all ADEs of all drugs combined was 1/0.78 of the rate in 1981, the first marketing year of temazepam.

Taking the reporting rate of all ADEs of all drugs combined in the corresponding marketing year of temazepam as the reference, the adjusting factor $f_{(j)}$ for the secular trend of reporting of the nine years between 1983 and 1991 can be calculated by (reporting rate of all ADEs of all drugs combined in the marketing year of temazepam)/(reporting rate of all ADEs of all drugs in the corresponding marketing year of triazolam) and given in the last column of Table 6.

Let the adjusting factor be denoted by $f_{(j)}$ for the j th marketing year of triazolam and temazepam, respectively; the ratio adjusted for the secular trend, $RR'_{(j)}$ is then defined by

$$RR'_{(j)} = r_{1(j)}f_{(j)} / r_{2(j)}$$

$P'_{(j)}$, the proportion of triazolam prescriptions adjusted for the secular trend, is $s_{1(j)} / (s_{1(j)} + s_{2(j)}f_{(j)})$. Here Z statistics and the confidence limits are calculated accordingly.

Table 5 ADE Reports of Amnesia for Triazolam and Temazepam, by Year of Marketing

Fig. 2 All ADR reports with fitted regression and 95% confidence limits

Table 6 Expected Overall Reporting Rates and Adjusting Factor

Marketing year	Triazolam		Temazepam		Adjustment factor, $f_{(j)}^a$
	Calendar year	Overall rate	Calendar year	Overall rate	
1	1983	14.1	1981	11.0	0.78
2	1984	16.0	1982	12.4	0.78
3	1985	18.1	1983	14.1	0.78
4	1986	20.4	1984	16.0	0.78
5	1987	23.0	1985	18.1	0.79
6	1988	25.8	1986	20.4	0.79
7	1989	28.8	1987	23.0	0.80
8	1990	32.1	1988	25.8	0.80
9	1991	35.5	1989	28.8	0.81

$f_{(j)}^a$ = (Overall reporting rate for temazepam calendar year)/(overall reporting rate for triazolam calendar) for the same marketing year.

When combining all marketing years, the regular pooled ratio is calculated by

$$RR' = \frac{\left[\left(\sum_j x_{1(j)} \right) / \left(\sum_j s_{1(j)} \right) \right]}{\left[\left(\sum_j x_{2(j)} \right) / \left(\sum_j s_{2(j)} f_{(j)} \right) \right]} \quad (6)$$

The Mantel–Haenszel ratio and the Z statistics can be derived as

$$RR'_{MH} = \sum_j \left[x_{1(j)} (1 - P'_{(j)}) \right] / (x_{2(j)} P'_{(j)}) \quad (7)$$

$$Z^* = \frac{\sum_j x_{1(j)} - \sum_j x_{2(j)} P'_{(j)}}{\sqrt{\sum_j x_{2(j)} P'_{(j)} (1 - P'_{(j)})}} \quad (8)$$

Table 7 presents the reporting rates of the first nine marketing years of the two drugs, stratified by marketing year and adjusted for the secular trend.

After being adjusted for the marketing year and the secular trend of reporting, the amnesia reporting rate of triazolam was reduced from 45 folds (Mantel–Haenszel statistic in Table 3) to about 29 folds (Mantel–Haenszel statistic) of the rates of temazepam.

Note that:

1. in order to adjust for the marketing year, the data of the ADE reporting of temazepam in the marketing years beyond the latest marketing year of triazolam were not used;
2. the adjustment of secular trend is determinative without using the estimation error of the estimate;
3. as stated in the last section, usage of the drug is an estimate with standard error that was not accommodated in the analysis;

^aRxs: in 1000 prescriptions.

^bPer 1 million prescriptions, triazolam rate adjusted for overall reporting rate difference in 2 years.

^c(Rate of triazolam)/(rate of temazepam).

- adjusting for marketing year and secular trend gives a more conservative signal for high ADE reporting than without adjustment of the drug of interest that is marketed more recently than its control;
- signaling high ADE reporting rate through comparison between drugs could be sensitive to the difference in patient population and the difference in ADE reporting pattern of the two drugs.

Generalized approaches for signaling of high ADE reporting rate in comparison with multiple control drugs were also proposed by Rossi et al.,^[13] Hsu,^[14] and Tsong.^[15]

SIGNALING REPORTING PROFILE DIFFERENCE

As noted in the last section, although the data are rich in the AERS system, there is no appropriate denominator information for incidence rate estimation. As a surrogate, the ADE reporting rate per million prescriptions is used in signaling the relative safety of a drug product with the appropriately selected comparative drug or drugs. The usage estimate used in the estimation is often obtained from data vendors. The process can be costly and time consuming. It is often unfeasible when the drugs studied had a long marketing history or when many drugs are used in the comparative group. In that case, sometimes signaling unusual reporting pattern may be informative and can be performed without using the estimation of patients or

usage. For example, safety concerns of stroke risk associated with treatment with phenylpropanolamine was signaled by the extremely large proportion of the ADE reports in a 2-by- k frequency table display of celebravascular artery (CVA) event report vs. other reports by drug product as in [Tables 8](#) and [9](#). The data were presented at the FDA Advisory Committee Meeting of Over-the-Counter Drug Products in October 2000.

Signaling of outlying reporting profile or testing for reporting profile difference between drugs is also of interest and often used in postmarketing surveillance monitoring. [Table 10](#) shows an example of the comparison of the ADE reporting profiles of triazolam and temazepam in order to assess concerns that the ADE profile of triazolam may be different from other drugs of the same class. A chi-square test was used for testing $H_0: P_{ik} = P_{2k}$, $k=1$ to K , with P_{ik} representing the proportion of reports of the k th ADE. The data were presented at the Meeting of the FDA Advisory Committee on Neuropharmaceutical Drug Products held in 1992.

Signaling of reporting profile difference was also often used in comparisons between genders, age groups, and two drugs.

DATA MINING FOR ADE SIGNALING

When a large database of spontaneous reports of adverse reactions is considered, there are other practical needs

Table 8 Phenylpropanolamine (PPA) and CVA Reports in Women Aged 10–59 Years (1977–January 1991)

for the events evaluator beyond statistics. The first is the ability to assess the patterns of the patients’ experience with the drug product. The second is the need to advance the understanding of drug-associated events. Thus techniques that will enhance the ability to address these needs, such as data mining and visualization tools, have been introduced.^[16,17,22]

The approach that the FDA began to explore in 1998 was originally developed by William DuMouchel^[16] of AT&T. In the last four years, refinements have been made to the methods, the speed of access to the database, and the performance of the computations. The approach was also enhanced by coupling the data-mining software with visual graphics software for displaying the results. The data-mining model developed by the FDA^[17,18] consists of the following components:

1. FDA’s routinely updated structured database of ADE reports.

2. A model to extract AERS data records and format information for data-mining analysis.
3. Data-mining statistical algorithms.
4. Custom-designed software to display several kinds of visual graphics.

Pairwise Association

The basic statistic consideration is to consider the complete database as a large frequency table with drug product (more than 1400 products) as the row factor and AE (more than 950 different events) as the column (Table 11). The column margins, D_i ’s, are the total number of reports of the events. The row margins, A_j , are the total number of reports of the drugs.

When there is no association between drug and event of the reports in the database, p_{ij} , the proportion of the reports of a specific event j , among all reports of the drug product i , should be equal to A_j/n , the proportion of all reports of the specific event among all reports of all drugs. In other words, under the “no-association” hypothesis, the expected number of reports of event j of a given drug i is the proportion of all reports in the selected event of all $E_{ij}=D_i A_j/n$. The association is measured by

$$(O/E)_{ij} = n_{ij}/E_{ij} = n_{ij}n/D_i A_j \quad (9)$$

This association is the measurement of information connecting the i th drug to the j th event in the reporting system.

The empirical Bayes procedure introduced by DuMouchel^[16] in ADR data mining would consider each n_{ij} as a sample observation from a Poisson distribution with unknown mean μ_{ij} . The interest in data mining is focussed on $\lambda_{ij}=\mu_{ij}/E_{ij}$. The approximately 1400·952 λ_{ij} ’s are sampled from a common prior distribution that is a mixture of two gamma distributions as follows,

$$\pi(\lambda; \alpha_1, \beta_1, \alpha_2, \beta_2, P) = Pg(\lambda; \alpha_1, \beta_1) + (1-P)g(\lambda; \alpha_2, \beta_2)$$

Table 11 Drug-Event Report Frequency in SRS Database

Drug	Adverse event						Total
	1	2	...	J	...	952	
A	n_{a1}	n_{a2}		n_{aj}		n_{a952}	D_a
B	n_{b1}	n_{b2}					D_b
⋮							⋮
I				n_{ij}			D_i
⋮							⋮
1400							D_{1400}
⋮							⋮
	A_1	A_2	...	A_j	...	A_{952}	n

where $g(\lambda; \alpha, \beta)$ is the density of the gamma distribution with mean $= \alpha/\beta$ and variance $= \alpha^2/\beta$, and P is the proportion of mixture.

$$g(\lambda; \alpha, \beta) = \beta^\alpha \lambda^{\alpha-1} e^{-\beta\lambda} / \Gamma(\alpha)$$

The five parameters ($\alpha_1, \beta_1, \alpha_2, \beta_2, P$) are determined by the observed data. For a given λ and E , the marginal distribution of each N_{ij} is a mixture of negative binomial distributions,

$$\Pr(N_{ij} = n_{ij}) = Pf(n_{ij}; \alpha_1, \beta_1, E_{ij}) + (1-P)f(n_{ij}; \alpha_2, \beta_2, E_{ij})$$

with

$$\begin{aligned} f(n_{ij}; \alpha, \beta, E_{ij}) \\ = (1 + \beta/E_{ij})^{-n} (1 + E_{ij}/\beta)^{-\alpha} \Gamma(\alpha + n_{ij}) / \Gamma(\alpha) n_{ij}! \end{aligned}$$

In addition, the posterior distribution of each λ after observing n_{ij} is a mixture of two gamma distributions with modified parameters,

$$(\lambda | N_{ij} = n_{ij}) \sim \pi(\lambda; \alpha_1 + n_{ij}, \beta_1 + E_{ij}, \alpha_2 + n_{ij}, \beta_2 + E_{ij}, Q(n_{ij}))$$

where $Q(n_{ij})$ is the posterior probability that λ came from the first component of the mixture, given n_{ij} . It is given by

$$\begin{aligned} Q(n_{ij}) = Pf(n_{ij}; \alpha_1, \beta_1, E_{ij}) / [Pf(n_{ij}; \alpha_1, \beta_1, E_{ij}) \\ + (1-p)f(n_{ij}; \alpha_2, \beta_2, E_{ij})] \end{aligned}$$

The posterior expectation of λ and $\log(\lambda)$ given n_{ij} are given by

$$\begin{aligned} E[\lambda | N_{ij} = n_{ij}] = Q(n_{ij})(\alpha_1 + n_{ij}) / (\beta_1 + E_{ij}) \\ + (1 - Q(n_{ij}))(\alpha_2 + n_{ij}) / (\beta_2 + E_{ij}) \end{aligned}$$

and

$$\begin{aligned} E[\log(\lambda) | N_{ij} = n_{ij}] = Q(n_{ij})[\Psi(\alpha_1 + n_{ij}) \\ - \log(\beta_1 + E_{ij})] + (1 - Q(n_{ij})) \\ \times [\Psi(\alpha_2 + n_{ij}) - \log(\beta_2 + E_{ij})] \end{aligned}$$

where $\Psi(x)$ is the digamma function. The empirical Bayes measure used in data mining cell counts ranking is defined as

$$\begin{aligned} \text{EBlog} 2_{ij} = E[\log_2(\lambda_{ij}) | N_{ij} = n_{ij}] \\ = E[\log(\lambda_{ij}) | N_{ij} = n_{ij} / \log(2)] \end{aligned}$$

The quantity $\text{EBlog} 2_{ij}$ is a Bayesian version of $\log_2(O/E)_{ij}$.

For large E_{ij} and $(O/E)_{ij}$, $\Psi(x) \approx \log(x)$, and $\log(\alpha + n_{ij}) - \log(\beta + E_{ij}) \approx \log(n_{ij}/E_{ij}) = \log(O/E)_{ij}$. A quick-and-dirty 95% approximate confidence interval of λ_{ij} was proposed by DuMouchel^[18] as follows,

$$\text{EBGM}_{ij} \exp\left\{-2/\sqrt{(n_{ij}+1)}\right\} \lambda_{ij}$$

$$\text{EBGM}_{ij} \exp\left\{2/\sqrt{(n_{ij}+1)}\right\}$$

where $\text{EBGM}_{ij} = 2^{\text{EBlog}2ij}$.

Rankings of $\text{EBlog}2_{ij}$ or EB05 ($\approx \text{EBGM}_{ij} \exp\{-2/\sqrt{(n_{ij}+1)}\}$), the lower 95th confidence limit of λ_{ij} , are used for signaling purposes.

Multi-Item Association

When dealing with the reports of multiple drugs and events, the interest is on the number of reports instead of the independent drug–event combinations as used in $\text{EBlog}2_{ij}$. To address this, DuMouchel and Pregibon^[23] proposed to consider the problem within the framework of the so-called market basket problem. Assume that there is a maximum of three drugs and K ADEs mentioned in each report, under such framework, let n be the total number of reports, $i(1)$, $i'(2)$, $i'''(3)$, be the index of the first to the third drug associated with the report with the restriction that $i(1) < i'(2) < i'''(3)$, and $j_1, j_2, \dots, j_K$ be the index of the first to K th ADE mentioned in the report with the restriction that $j_1 < j_2 < \dots < j_K$, respectively. Let the frequency of the item sets of size 1 drug and 1 ADE up to four drugs and 4 ADE be denoted by $n_{i(1),j_1}$, $n_{i(1),i'(2),j_1}$, $n_{i(1),j_1,j_2}$, ..., $n_{i(1),i'(2),i'''(3),j_1,j_2,j_K}$, respectively. Note that

$$D_i = \sum_{i(1)=i, \text{ or } i'(2)=i, \text{ or } i'''(3)=i} \left[n_{i(1),i'(2),j_1} + n_{i(1),j_1,j_2} + \dots + n_{i(1),i'(2),i'''(3),j_1,j_2,j_K} \right]$$

$$A_j = \sum_{j_1=j, \text{ or } j_2=j, \text{ or } \dots, \text{ or } j_K=j} \left[n_{i(1),i'(2),j_1} + n_{i(1),j_1,j_2} + \dots + n_{i(1),i'(2),i'''(3),j_1,j_2,j_K} \right]$$

Then, proportions of a given drug i or a given ADE j , under the hypothesis that there is a null association between drug and ADE, are

$$P_i = D_i/N$$

$$P_j = A_j/N$$

respectively.

The expected frequencies for the drug-ADE item under the null association hypothesis are

$$E_{ij} = N P_i P_j, E_{iij'} = N P_i P_j P_{j'}, E_{iij'j''} = N P_i P_j P_{j'} P_{j''}, \dots$$

Hence (O/E) 's can be calculated. The multi-item empirical Bayes shrinkage of (O/E) 's can be carried out using the same procedure as described in the "Pairwise Association" section.

The drug-ADE of all cells in the database is ranked by the size of the Bayes shrinkage of (O/E) . A preliminary signal is generated when the adjusted measure association has a value greater than a predetermined threshold. A preliminary signal is then examined by reviewing the information displayed via computer graphics before a signal is issued for verification information.

As discussed in the last section, data-mining signaling is not signaling safety concerns based on incidence estimates (i.e., adjusted for patient population) or the surrogate estimates such as the reporting rate (i.e., adjusted for usage). It is rather signaling the outlying or unusual reporting of a specific drug-ADE among the ADE reporting of the specific drug in the sense that the reporting profile of this specific drug is outstanding. The difference between the results of the two types of signaling may be illustrated with the data of the reporting of the central nerve system or the psychologic ADE of triazolam and temazepam (see Table 12 and Table 13). For the nine ADEs, the usage adjusted reporting rate of triazolam ranks higher than the rate of temazepam (Table 12).

However, without usage adjustment, of three ADEs (i.e., agitation, depression, and fatality) the O/E of temazepam ranks the highest among the 18 O/E in Table 13. The ratios of the rates (Fig. 3) have the same profile as that of the ratio of O/E 's (Fig. 4) but with much smaller magnitude. In contrast to triazolam, the ratio of O/E is less than 1 in three ADEs. The difference in magnitude can be explained by the difference in usage and the difference in the reports of the two drugs. Actually, the ratio of the number of ADE reports of triazolam to temazepam, 18.32 (=1850/101), is 11.24 times the ratio of the usage, 1.63 (=66,547/40,710). The ratio equals exactly the ratio of the reporting rate ratio to the O/E ratio of any ADE shown in Figs. 3 and 4. The signaling based on O/E would be the same as the signaling based on reporting rate (which is often considered as surrogate of incidence density rate) when the ratio equals 1.

Szarfman^[18,19] reported the correlation between usage and the number of ADE reports of some selected drug categories. The correlation ranges from 40% in antineoplastic and in antiviral drug class to over 90% in each of cardiac, antihypertensive, antidiabetics, antilipemics, antihistamines, lung smooth-muscle relaxants, and anticoagulants drug class. The overall correlation is about 63%. This suggested the heterogeneity of the reporting rates among the drug classes. In addition, it is also logical to consider that the reporting profiles in terms of what to report are different among the drug classes. The heterogeneity among the drug classes suggests that refinement needs to focus on the subdatabase instead.

CONCLUSION

The history of postmarketing adverse drug event signaling has been long and the spontaneous reporting database has been criticized, ignored, and often misused over the years. Yet because of its size of information and timeliness, it saved countless lives by the alerts generated from it and the follow-through using this imperfect system. The experienced FDA spontaneous report handlers and analysts can often generate an initial drug-event signal by simply noticing the unusual reporting pattern, unusual changes of the reporting pattern, or the high volume of reports of a drug among the drugs of a similar category or for the similar indications. For example, if a drug was approved for marketing under some stringent risk management plan, an increased frequency of reporting is a signal of potential failure of the risk management plan. There are numerous examples where a sponsor withdrew a drug from the market due to the follow-through initiated by a strong early marketing signal generated from a simple table such as Table 7 or Table 8. In the case of our example, PPA was used as the over-the-counter drug product under the grandfather law and manufacturers were not required by law to submit the report to the FDA. Most of the cases were reported directly by medical professionals. Because of the weakness of the spontaneous reporting data, the strength of the initial signal was not well received by professionals. The risk was verified by a large scale prospective case-control study conducted by a research group lead by a Yale University epidemiologist to verify risk. It took almost ten years for the study design, data collection, and analysis to be completed.

There are many versions of the methods similar to the one reported in the section “Signaling of High Reporting Rate,” for detecting the signal of a high reporting rate of a given drug-event. The one reported in this article is one of the most stringent procedures to adjust for the factors that were estimable. The results of Table 7 were interpreted

based on the assumption that the patient populations and prescription patterns of the two drugs were comparable. A calibration constant may be used when the prescription patterns are different. In fact, when the clinical trial data were reanalyzed, a better understanding of equivalent dose of the two drugs was taken into consideration and the relative risk was found much smaller and not statistically significant.

Supporters of using signaling procedure without estimate of patient population often criticize the precision and reliability of the estimate. However, what was used in the signaling procedures of increased frequency of reporting and high reporting rate are the ratio of usage estimates that serve as the estimate of ratio of patient population sizes. In practice, once a drug of interest is identified for monitoring, the FDA will take steps to collect information on the usage of the drug of interest and its comparison drug(s).

As stated earlier, the interpretation of a signal for risk requires the estimate of ratio of patient populations. Signaling procedure based on data-mining is a useful tool to generate signals for an unusual reporting profile. Basically, it is an early signaling procedure before a drug of interest is identified for monitoring. However, the capability of using a data-mining tool to study drug–drug interaction in a large database makes its utility much more promising for some advanced application in post-marketing adverse event signaling.

Postmarketing Surveillance

Patricia B. Cerrito

University of Louisville, Louisville, Kentucky, U.S.A.

Abstract

Once a drug is released on the market, it can be used for a variety of illnesses that were not in the original randomized testing process. Therefore, there are several questions that must be answered through postmarketing surveillance. This entry will focus on investigative techniques to examine these issues.

INTRODUCTION

Drugs are not approved for general use until they go through an elaborate testing period. The “gold standard” of randomized, controlled trials must be utilized for drugs to be granted approval. However, once a drug is released on the market, it can be used for a variety of illnesses that were not in the original randomized testing process. It can be prescribed to a general population that was previously excluded from the study subjects. Therefore, there are several questions that must be answered through postmarketing surveillance. Problems to be considered include (1) the effects on previously excluded subpopulations, (2) the cost effectiveness of the new drug compared to older treatments, and (3) the occurrence of previously unknown adverse events. This article will focus on investigative techniques to examine these issues.

OVERVIEW

The first such problem is to determine the effects of the drug on populations previously excluded from the randomized trials. Two populations that are virtually routine to exclude are children and pregnant women. Studies generally recruit few in minority populations.^[1] This can usually be extended to the exclusion of women who might become pregnant; that is, to exclude women of childbearing age. However, once a drug is approved for use, exclusion criteria no longer exist. A drug can be prescribed for anyone for any problem. A physician may have to assume liability when prescribing a drug for a nonapproved use, unless sufficient support exists in the medical literature for treatment. There is no liability for extending use to a segment of the population not previously studied.

Clinical trials by their nature must have an ending point. Usually, even Phase III clinical trials last a few weeks,

possibly a few months, rarely several years. However, particularly if the medication is prescribed for chronic problems, patients can take the medication for 30, 40, or 50 years. There might be possible long-term effects that are not seen in the short-term trials. Also, adverse reactions are rare; they will not always become apparent in clinical trials. The power analysis that determines the sample size for the clinical trial is defined in terms of the main effect; a much larger sample would be required to examine rare occurrences. This must be carefully monitored in postmarketing surveillance.

Another problem to be examined is that of cost-effectiveness. A new drug does not ordinarily treat a new illness; it usually has a claim to be more effective or safer than drugs currently in use. However, sometimes the effects are relatively similar. In this case, it is necessary to examine the cost of providing the benefit to the patient. This becomes particularly crucial as health management plans are devising formularies and limiting the drugs that can be used for treatment.

Each of these problems must be addressed through methodology and through data collection concerning drugs as they are used on the general population in postmarketing surveillance. For the researcher, statistical methods and data-mining techniques that can be used on observational data must be used. For the practicing clinician, there must be a way to record data from patients. For both, there is need to understand information in the medical literature that reports on postmarketing surveillance results.

DATA COLLECTION

The quality of the data generally depends upon the examination of the four parameters of hypothesis testing: significance level, power, effect size, and sample size. There are a number of ways that data can be collected in

Table 1 Quality of Evidence Collected in Postmarketing Surveillance

Level of evidence	Description	Treatment recommendation
I	Large, phase IV randomized, controlled trials patients	A. Should prescribe treatment to patients
II	Smaller randomized, controlled trials with low power so that the results are not necessarily conclusive	B. Should prescribe treatment to patients
III	Nonrandomized trial; contemporaneous controls	C. In the absence of severe adverse effects, should prescribe treatment
IV	Nonrandomized trial; historical controls	C
V	Uncontrolled studies, case series	C

From Ref. [2].

postmarketing surveillance. [Table 1](#) provides a chart of the quality of evidence.^[2] When there is any evidence to indicate that a patient might benefit without undue risk, the treatment should be tried, particularly if that treatment is not only very low risk but also of low cost.

It is important to examine any study for methodological flaws or for insufficient sample size, particularly if the results are negative. The power of a statistical test is the probability that it will lead to the rejection of the null hypothesis. It is desirable, although impossible, to have a small level of significance and a large power simultaneously without specifying a level of indifference (where two drug treatments are so close in effect that the investigator is indifferent as to outcome). Then the sample size is chosen. However, when small numbers of patients are used, the power will be low.

Observational studies (which include all studies without randomized controls) are particularly subject to confounding. This occurs when two variables examined are directly related to a third variable unexamined. The possible existence of a confounding factor can completely void the conclusions of the study. Therefore, great care must be taken to collect data on any known or suspected confounders.

POSTMARKETING QUESTIONS

Traditional methods of statistical analysis have focused on a very small number of variables^[3] utilizing a technique such as Bayesian analysis or logistic regression. More recently, data-mining techniques such as neural networks, fuzzy logic, and decision trees have been used:

Traditional model building is based on the use of rigorous statistical techniques such as multiple linear regressions. In contrast, neural networks are “adaptive computing,” in that they learn from data to build a model to explain an application or biological system. (There are no a priori assumptions of a linear relationship among variables.) A neural network is designed from the application, not the other way around. Applications may be simple or complex and linear or nonlinear such as in finance or other noisy systems (i.e., highly variable) where the relationship between variables is not in a straight line.^[4]

And stated in Ref. [5]:

The experienced statistician, perhaps the most capable of guiding the development of automated tools for data analysis, may also be the most acutely aware of all the difficulties that can arise when dealing with real data. This hesitation has bred skepticism of what automated procedures can offer and has contributed to the strong focus by the statistical community on model estimation to the neglect of the logical predecessor to this step, namely model identification.

The statistician’s tendency to avoid complete automation out of respect for the challenges of the data, and the historical emphasis on models with interpretable structure, has led that community to focus on problems with a more manageable number of variables (a dozen, say) and cases (several hundred typically) than may be encountered in statistical problems, which may be orders of magnitude larger at the outset. With increasingly huge and amorphous databases, it is clear that methods for automatically hunting down possible patterns worthy of fuller, interactive attention are required. The existence of such tools can free one up to, for instance, posit a wider range of candidate data features and basis functions (building blocks) than one would wish to deal with, if one were specifying a model structure “by hand.”

It is becoming increasingly clear that the more traditional techniques are not adequate in postmarketing surveillance. The algorithms developed through data mining examine databases with a set of built-in processes that automatically test hypotheses to generate interesting and unexpected rules and graphs that characterize the database. The automatic hypotheses-formation and -testing cycle continues until important rules and patterns emerge. It is up to the investigator to verify the significance of each rule and pattern.

Once the model has been identified, the verification process needs to begin. An outline of the process is given in [Table 2](#).^[6]

Drug Interactions

There are a number of statistical models that can be used to determine risk factors associated with medication use in the general population. The primary difficulty is to determine the approximate size of the population taking the medication. Unlike other developed nations, the United

Table 2 Process for Verifying an Identified Model

Procedure	Rationale
Developing an understanding of the application domain, the relevant prior knowledge, and the goals of the end user	What are the goals? What performance criteria are important? Will the final produce of the process be classification, visualization, summarization, prediction? Is understandability an issue? What is the trade-off between simplicity and accuracy?
Creating a target data set, selecting a data set, or focusing on a subset of variables or data samples on which discovery is to be performed	This involves consideration of homogeneity of the data, change over time, sampling strategy, etc.
Data cleaning and preprocessing	This involves the removal of noise or outliers, deciding on strategies for handling missing data fields, etc.
Data reduction and transformation	This involves finding useful features to represent the data, depending on the goal of the task; using dimensionality reduction or transformation methods to reduce the effective number of variables under consideration or to find invariant representations for the data; and projecting the data onto spaces in which a solution is likely to be easier to find.
Choosing the data-mining task	Deciding whether the goal is classification, regression, clustering, summarization, modeling, etc.
Data mining	The actual analysis, automated and most often done with software; includes neural network analysis.
Evaluating output	Determining what is actually knowledge and what is “fool’s gold.” Knowledge must be filtered from other outputs. This can be done by using statistical checks, visualization, or expertise.
Incorporating knowledge into the performance system	Checking and resolving potential conflicts with previously extracted knowledge.

From Ref. [6].

States does not have a national prescription registry to make it possible to track such information.

Once a population estimate has been made, the following variables need to be collected:^[7]

D = dosage and schedule taken over the time interval $[0, T]$

A = set of patient attributes

E = adverse event type

Then it is possible to estimate the conditional probability of E given the values of D , A , and T . There are a number of methods suggested for making an estimate. One that takes into consideration the fact that reported data are often dependent in various ways is that given in Cerrito and Cerrito.^[8] Define the vector (X, Y, T) , where

X = drug benefit

Y = drug risk (Table 3)

T = duration of medication use

The data collected are assumed to be from a weakly dependent set. In this way, the patient attributes needed in the model of Ref. [7] can be omitted. Then the probability density function of the vector (X, Y, T) can be estimated by

$$\hat{f}(x, y, t) = \frac{1}{na_n^3} \sum_{j=1}^n k\left(\frac{x - X_j}{a_n}, \frac{y - Y_j}{a_n}, \frac{t - T_j}{a_n}\right)$$

where

$k(\dots)$ = known multivariate function, called the kernel function

$(X_1, Y_1, T_1), \dots, (X_n, Y_n, T_n)$ = collected observations

a_n = constant smoothing parameter depending on n

Suppose it is only possible to define risks in terms of discrete categories $\{1, 2, \dots, m\}$. Suppose category 1 represents the most serious risk and category m represents the least serious so that the risks can be ordered. The standard scale is as shown in Table 3.^[9] Then a discrete estimator developed by Ahmad and Cerrito^[10] can estimate the discrete risks at each interaction level:

$$\hat{f}(x, y, t) = \frac{1}{na_n^2} \sum_{j=-\infty}^{\infty} W(\hat{s}_n, i, j) \sum_{l \in C_n(l)} k\left(\frac{x - X_l}{a_n}, \frac{t - T_l}{a_n}\right)$$

Table 3 Standard Scale for Risk

Significance rating	Severity	Documentation
1	Major: The effects are potentially life-threatening or capable of causing permanent damage	Suspected or established
2	Moderate: The effects may cause a deterioration in a patient's clinical status; additional treatment may be necessary	Suspected or established
3	Minor: The effects are usually mild; consequences may be bothersome or unnoticeable	Suspected or established
4	Major/moderate	Possible
5	Minor	Possible
	Any	Unlikely

From Ref. [9].

where $C_n(j) = \{\text{indices } l \text{ such that } (X_l, Y_l, T_l) \text{ is such that } Y_l \text{ is in category } j\}$. The function $W(s, i, j)$ is a discrete window weight function defined on $S \times J \times J$, where S is an interval on the real line and $J = \{\dots, -1, 0, 1, \dots\}$ satisfying^[11]

$$W(0, i, j) = \begin{cases} 0 & i \neq j \\ 1 & i = j \end{cases}$$

It has been shown^[12] that the choice of the kernel function will not significantly alter the outcome. The choice of the smoothing parameter can have significant impact. Techniques have been developed to optimize the choice of this parameter. However, because the outcomes are discrete, various smoothing parameters can be attempted and investigated using ROC curves (for exactly two outcomes)^[13] or by using the standard training/testing/validation process routinely used in neural network analysis.^[14] The misclassification rate (m1) of the training set is compared to the misclassification rate of the testing set (m2). If $m1 < m2$ then the value of a_n is adjusted upward. The goal is to have m1 and m2 within a small interval of each other.

The commercially available NeuralWare II from Aspen-Works, Inc., does perform kernel density estimation. In addition, PROC DISCRIM and PROC KDE in SAS from SAS Institute, Inc., will perform kernel density estimation. For an adaptation of the discrete-continuous parameter, the symbolic computational software Mathematica from Wolfram, Inc., can easily be used to develop the necessary programming code to perform the required algorithm. Suggestions of such Mathematica code are given in the [Appendix](#) to this entry.

Excluded Populations

Although some populations (pregnant women and children) are routinely excluded from clinical trials because of risk and liability issues, still other groups are indirectly excluded because of small numbers of volunteers. Yet it is clear that race and ethnicity do have an impact on the pharmacokinetics of drugs.^[1] Bioavailability (F) has three determinants, $F = f_a f_g f_h$, where

f_a = fraction of drug absorbed
 f_g = fraction escaping gut metabolism
 f_h = fraction escaping hepatic first-pass metabolism

Studies that have compared drug absorption for different races have demonstrated that there is no difference when drug absorption is passive. However, when the drug undergoes active absorption, there are statistically significant differences. Studies comparing racial groups have had different outcomes for different drugs, making generalizations impossible.^[15] Differences in absorption can result in differences in effect for different populations. In this case, the model defined in the previous section ("Drug Interactions") needs to be expanded to include a vector Z of patient characteristics:

$$\hat{f}(x, y, z, t) = \frac{1}{na_n^3} \sum_{j=-\infty}^{\infty} W(\hat{s}_n i, j) \sum_{l \in C_n(j)} k\left(\frac{x - X_l}{a_n}, \frac{z - Z_l}{a_n}, \frac{t - T_l}{a_n}\right)$$

Another population generally excluded from clinical trials is the elderly. For this population, males average 13.26 different prescriptions; females average 16.25.^[16] Interaction studies typically examine two to three drugs in combination. It is necessary to develop tools that will investigate medications prescribed in such large numbers.

Cost-Effectiveness Analysis

Cost-effectiveness is a broad term that encompasses three major types of models:^[17]

- Cost-benefit studies. Both costs and outcomes are measured in dollars.
- Cost-effectiveness studies. Outcomes are quantified in terms of health status measures, such as the number of symptom-free days.
- Cost-utility studies. Effectiveness is measured in terms of utility, such as quality-adjusted life-years.

There are also different perspectives taken with regard to cost analysis. The broadest perspective is societal, where the interest is to define the greatest good for the greatest number of people (while possibly increasing risks for some individuals). An intermediate perspective belongs to an insurer or a health maintenance organization. The narrowest perspective belongs to an individual patient or an individual provider. These perspectives can sometimes be at odds.

The different perspectives will clash, for the broader viewpoints will sometimes be at the expense of individuals. Health maintenance organizations tend to deny any treatment without Level I (or possibly Level II) evidence. Oregon attempted to prioritize its Medicaid funding based on optimizing results from a societal perspective. The program failed because the societal perspective often differed considerably from the individual perspective.^[18]

In each case, an attempt is made to quantify health outcomes, usually assuming a linear relationship. In addition, most cost-effectiveness analysis depends upon rough estimates of probabilities, usually provided by the "Delphi interview method." This involves asking a group of experts for their perceptions. Real data are rarely used to develop the model. Instead, a sensitivity analysis is performed. The estimates given by the experts are altered to determine just how much deviation will still give the same outcomes (a measure of robustness). However, as in the case of peptic ulcers, if the experts were unaware of the actual cause of an illness, the sensitivity analysis would not provide an accurate response. Therefore, cost-effectiveness analysis will always support conventional belief.

The model for examining cost takes a form similar to the one described under "Drug Interactions" in this

section. There is a vector (E, C, Z) where E = effects (both benefits and risks), C = costs, and Z = patient characteristics. Then if a linear relationship is assumed, it is defined by the equation

$$e_{ij} = G_j(c_{ij}) + \varepsilon_{ij}$$

However, costs from a societal perspective are assumed to stay within 2 standard deviations of the mean. Unfortunately, health care has much to do with outliers, i.e., individuals at the extreme end of need, who use health care resources way beyond this preset norm. Therefore, it is preferable to use a nonlinear model with

$$\hat{f}(e, c, z) = \frac{1}{na_n^2} \sum_{j=-\infty}^{\infty} W(\hat{s}_n, i, j) \sum_{l \in D_n(l)} k\left(\frac{c - C_l}{a_n}, \frac{z - Z_l}{z_n}\right)$$

assuming that E takes discrete values.

EXAMPLES FROM THE MEDICAL LITERATURE

Surveillance of *Helicobacter pylori* Treatments

The problem of peptic ulcers is one of extreme interest. For years the standard treatment was to use an acid inhibitor such as omeprazole or ranitidine. It was assumed that the underlying cause of ulcers was stress. Therefore, it was also assumed that a maintenance dose of medication was required to prevent recurrence or that stress-reduction therapy would be needed to prevent additional problems. It was also assumed that bacteria could not survive in the stomach, so until recently no studies were conducted to investigate the possibility of infection.^[19] The discovery of *H. pylori* in the stomach completely changed the entire course of investigation. Therefore, it is possible to examine all aspects of postmarketing surveillance in the investigation of the treatment and outcome of peptic ulcer disease, particularly because all medications used to treat the problem were fairly common and already approved for use for other illnesses.

Drug Interactions

Once it was discovered that *H. pylori* could survive in the acidic environment of the stomach, studies were conducted to determine a treatment that could successfully eradicate it. All studies involved postmarketing surveillance, for all drugs tested were already approved for use. Decisions were made early on to use drugs in combination: various antibiotics and acid suppressors. Penston^[20] focused on the combination of omeprazole, amoxicillin, and metronidazole. Others^[21–24] examined other combinations. No study has shown that these combinations put patients at risk for serious adverse reactions. Table 4,^[2] summarizes the level of evidence for eradicating *H. pylori* for a variety of gastrointestinal complaints. Treatment is recommended for

Table 4 Level of Evidence for Eradicating *H. pylori*

Complaint	Level of evidence	Recommendation
Peptic ulcer	I	Treat
Bleeding duodenal ulcer	I	Treat
Nonulcer dyspepsia	II	Treat
Early gastric cancer	III	Treat
Gastric mucosa-associated lymphoid tissue	V	Treat
Gastroesophageal reflux disease	Below Level V	Do not treat

From Ref. [2].

levels III–V because it has low risk and low cost and there is little indication that another treatment is more effective (Table 4).

Another type of interaction to examine occurs when different problems occur simultaneously. Stress ulcers still occur, particularly in an intensive care unit. Rune^[25] explored the possibility that *H. pylori* contributed to the incidence of stress ulcers. Examining 874 patients (sufficient numbers for 90% power), the presence of *H. pylori* was found to be statistically significant.

Long-Term Follow-Up

Since acid suppressors were developed as the standard treatment for peptic ulcers, a study^[26] was conducted to determine the long-term treatment results for peptic ulcers. The results demonstrated clearly that the traditional measures of acid suppression and surgery were somewhat temporary; the majority of patients still had gastric problems. This study was not completed until years after the discovery of *H. pylori*. Yet none of the subjects followed was given a test for the presence of the bacteria; none were treated for the infection. It is very speculative that this occurred, because physicians are still generally reluctant to prescribe triple therapy^[27] or because of a reluctance to stop the study early. However, if this study had been initiated at an earlier time, there should not have been so much complacency concerning the effectiveness of acid suppressors in treatment. Patients with recurring problems should not have been so casually dismissed as having stress disorders. No matter how much confidence exists in a particular treatment, there will always be unknowns that can drastically change the perspectives.

Excluded Populations

Caraco et al.^[15] conducted a study to compare absorption rates of omeprazole between Chinese and Caucasian subjects. The study concluded that the Chinese had greater bioavailability of the drug. It is suggested that Chinese patients should routinely receive a lower dose of the drug

to compensate for the greater bioavailability. It is not suggested what that dose should be. It also remains unknown just how this absorption rate of omeprazole affects the triple therapy routinely used to eradicate *H. pylori*.

Another study^[28] was conducted to investigate the problem of ulcers in the elderly population. A sample of 121 patients ranging in age from 61 to 89 years was treated with omeprazole and with one or two antibiotics for 3 or 7 days. There was a total of six different combinations. This study has sufficient power (80%) to detect a 15% difference in outcome with a 5% level of significance. The study also resulted in 5% of the subjects with adverse reactions to the medications. The optimal treatment was omeprazole, clarithromycin, and metronidazole for 7 days.

Cost-Effectiveness Analysis

Since acid suppressors were developed to treat ulcers, a cost-effectiveness analysis was conducted to compare this treatment with the triple therapy used to eradicate *H. pylori*.^[29] This study obviously had to be done from a societal perspective, because the individual perspective would be a preference for complete eradication of the cause of the ulcers rather than to use lifelong maintenance therapy to relieve symptoms. The study did conclude that the societal perspective was identical to the individual perspective. Therefore, from all perspectives, eradication is cost-effective. Yet it is still little prescribed.^[27]

Greenberg et al.^[30] examined the need for routine endoscopy for patients with gastrointestinal problems. It is suggested that a trial of omeprazole should be made prior to routine endoscopy to reduce costs and to increase the effectiveness of endoscopy. For patients for whom omeprazole relieves symptoms but does not heal, a serology test for the presence of *H. pylori* should be done in place of endoscopy. O'Malley et al.^[31] investigated cost-effectiveness in a different way. The claim is made that many patients presenting with gastrointestinal complaints actually have psychiatric disorders. The claim is then made that screening for psychiatric disorders prior to upper endoscopy is cost-effective. However, of the patients diagnosed with a psychiatric disorder, 26% also had a medical problem. Of the patients with a disorder, 44% were diagnosed with somatoform that should not be diagnosed without first screening for a medical disorder. Out of the 116 patients in the study, none were tested for the presence of *H. pylori*.

Surveillance of Fluoxetine

There are a number of papers in the medical literature discussing postmarketing surveillance of this drug. Some^[32,33,34] discuss anecdotal case studies involving the use of fluoxetine. Without statistical evidence, it is not known whether the adverse effects reported in these editorials are actually caused by fluoxetine or are just

coincidental. Even if real, there is no way of knowing the actual risk, nor is there any way of knowing whether the risk is for a particular segment of the population. The most such letters can do is to make a practicing physician aware of the possibility of an adverse reaction.

Many of the postmarketing studies have examined segments of the population that were excluded from trials prior to FDA approval.^[35,36] Chambers et al.^[36] provide Level III evidence. Consider the method of recruiting subjects:

From 1989 through 1995, the California Teratogen Information Service and Clinical Research Program received approximately 1500 calls requesting information on the potential teratogenic effects of fluoxetine. An estimated one-third of these inquiries were made by pregnant women currently taking the drug. We selected 288 of these women for inclusion in the study on the basis of accessibility by telephone and willingness to participate. During this same period, pregnant women who called the program with questions about drugs and procedures not considered teratogenic—including acetaminophen use, dental radiography, and limited alcohol ingestion (< 1 oz [30 ml] of 100 percent alcohol per week before pregnancy was recognized)—were asked to enroll in the study as a control group. From this group, 254 women were selected as controls because their inquiries were closest in time to those of the women taking fluoxetine. The majority of women in each group were enrolled in the study during the first trimester of their pregnancies, and all were enrolled before any outcomes of the pregnancy were known, including knowledge of conditions that were diagnosed prenatally.

Each woman who enrolled in the study completed a questionnaire that included her history of previous pregnancies and family medical history, socioeconomic and demographic information for each woman and her partner, and exposures during the current pregnancy. The exposure history included dosages, dates, and indications for all medications; use of caffeine; use of supplemental vitamins; occupational exposures; infectious or chronic diseases; prenatal testing or other medical procedures; and use of recreational drugs, tobacco, and alcohol. Each woman was provided with a diary in which she was asked to keep a record of any additional exposures that might occur before delivery. We supplemented this record by calling the women throughout their pregnancies.

Only women who called for information were asked to participate. It was not determined if there were differences in the two groups of women, specifically in any socioeconomic variables; the control group was matched by length of gestation only. A power analysis is needed to determine if there is a sufficient sample size to detect differences in rare events. A severe adverse effect can be expected to occur in the population only 1–2% of the time. To detect even a 4% difference (from 10 per 1000 women to 14 per 1000 women) requires a total sample size of 1000 patients. There were only 482 women enrolled in the study. Moreover, fewer infants were evaluated for severe reactions, reducing

the sample size even more. This study was totally unable to determine if real differences in safety existed. In addition, a subgroup analysis was performed based upon trimester of exposure. Subgroup analysis should always be used to generate hypotheses, never to make inference.^[37] Yet this paper makes conclusions based upon this subgroup analysis.

CONCLUSION

There are a number of studies that must be conducted once a drug has been approved and marketed: long-term follow-up, additional diagnoses, previously excluded populations, and cost analysis. Most of these studies will involve the collection of observational data instead of randomized clinical trials. Statistical methods that can safely utilize such observational data must be used to generate a hypothesis. These methods include data mining and neural network analysis. Once the hypothesis has been generated, it must be validated by additional data.

Power

Kenneth B. Schechtman

Washington University School of Medicine, St. Louis, Missouri, U.S.A.

Abstract

The “power” of a statistical test is the probability of rejecting the null hypothesis when it is false. This brief entry summarizes statistical methods of analyzing this probability.

INTRODUCTION

The “power” of a statistical test is the probability of rejecting the null hypothesis when it is false. Closely related to statistical power is the false-negative rate, which is often referred to as the Type II error or beta error. The false-negative rate equals 1 minus the power. It is defined as the probability of not claiming statistical significance when the null hypothesis is false. A fundamental goal of every research protocol should be to define a study that has adequate statistical power and, thereby, a sufficiently small Type II error rate. Whereas there are no universally accepted guidelines, it is broadly accepted that a prospective study should not be initiated and is unlikely to be funded unless the statistical power that is associated with primary hypothesis tests is projected to be in the 0.8–0.9 range.

CORRELATES OF STATISTICAL POWER

Statistical power depends in obvious ways on several characteristics of the statistical test being performed. In addition to the sample size association, which is discussed next, the power of a statistical test depends also on the size of the between-group difference and on the amount of noise in the data. For example, the greater the difference between groups that are to be compared, the easier it is to establish statistical significance. Thus, statistical power is directly related to the magnitude of the failure of the null hypothesis. Similarly, the greater the variability in a quantitative measure, the greater is the noise in the data and the harder it is to establish significance. That is, an increase in the variance of a parameter implies a decrease in the statistical power of the associated hypothesis test.

STATISTICAL POWER AND SAMPLE SIZE

The most important correlate of statistical power is the sample size. An evaluation of the close relationship

between statistical power and sample size should be a key component of the design of every research protocol and of the interpretation of the resulting publications. Unfortunately, repeated reviews of the literature suggest that low power and inadequate sample size are extremely common, if not routine, in the medical literature.^[1–4] For example, Freiman et al.^[1] reviewed 71 randomized controlled trials whose primary conclusion was negative. They found that 67 of the 71 trials (94.4%) had greater than a 10% probability of missing a true 25% therapeutic improvement. That is, the power to detect a 25% treatment benefit was nearly always less than 0.9. The power to detect a very large treatment benefit of 50% was less than 0.9 in 70.4% of the reviewed papers. Although these authors do not present the precise results, it is clear from their tabulations that the power of many if not most of the reviewed hypothesis tests was such that clinically important differences in primary endpoints were more likely to be missed than to be reported as statistically significant. This suggestion that statistical power in the published literature is often extremely low is highlighted by Schechtman et al.,^[4] whose review of 37 papers on the surgical treatment of sleep apnea found that the median sample size would yield a power of under 0.2 to test key hypotheses of interest. When the power is this low, the claim that “there is no significant differences between groups” translates roughly into the more accurate assertion that “we have no idea if the two treatments are different in clinically important ways because the sample size was too small to address the question.”

In addition to confirming that many clinical trials are too small to detect large and clinically important differences, Moher et al.^[2] have noted that even in the most prestigious and carefully reviewed journals, there is a strong tendency to omit all discussion of sample size and statistical power. These authors reviewed the 383 randomized trials published in the *New England Journal of Medicine*, the *Journal of the American Medical Association*, and the *Lancet* in the years 1975, 1980, 1985, and 1990. They found that only 32% of the trials with negative results discussed statistical power and sample size calculations. This means

that unless the reader is energetic enough to do these computations independently, it may be difficult to determine whether negative conclusions mean that there are unlikely to be clinically important differences between groups or, alternatively, that the study was too small to address the question. This uncertainty is compounded by the fact that only 20 of the 102 negative studies that were reviewed in the Moher et al. paper made any statement as to the clinical significance of observed differences. The key bright spot in this report is that while the 0% rate at which sample size considerations were discussed in the reviewed 1975 publications mirrors the poor rates reported elsewhere at about that time,^[5,6] the more recent rate is a substantially improved 43% in 1990.

DETERMINING WHETHER A STUDY IS INADEQUATELY POWERED

Because they are discussed elsewhere in this volume, we do not focus on the many standard formulae that are commonly used to compute power and sample size. However, we demonstrate how an astute reader can quickly decide whether a study is too small using a standard unpaired *t* test as an illustration. Considerations similar to those described next can be applied in other settings.

The required per-group sample size *N* for an unpaired *t* test with the same number of patients in each group is computed using the equation

$$N = \frac{2(Z_{\alpha} + Z_{\beta})^2}{\Delta^2}$$

where Z_{α} is the standard normal deviate for a test with significance level α (e.g., $Z_{\alpha} = 1.96$ for a two-sided test at the 0.05 level of significance), Z_{β} is the normal deviate associated with a Type II error rate of β or a power of $1 - \beta$ (e.g., $Z_{\beta} = 1.28$ for a power of 0.9), and $\Delta = (\mu_2 - \mu_1)/\sigma$, where μ_1 and μ_2 are the means in the two groups and σ is the common standard deviation. The foregoing expression can be adjusted to compute the sample size in one of two groups when patient allocation is unequal by multiplying by $(r + 1)/r$, where r is the ratio of the total sample size to the sample size in the group of interest.

It follows from the foregoing equation that for a given significance level and a given statistical power, the required sample size depends totally on Δ , the ratio of the difference in means divided by the common standard deviation. Using the equation or the sample size tables that are presented in many statistics texts, it is easy to determine whether the sample size in a given study is reasonable. Thus, assuming a two-sided test at the 0.05 level of significance, a Δ of 1 means that 23 patients per group will yield a power of 0.9. If you are reading a paper where $\Delta = 1$ and the sample

size is 50 per group, it is overkill insofar as the relevant hypothesis test is concerned. If there are 10 patients in each group, the study is far too small unless Δ is in the 1.5 range. For smaller Δ s in the 0.5 range, 70 or so subjects must be studied in each group to yield adequate power. If a study with a Δ of 0.5 enrolls only 20 patients per group, a common state of affairs in much of the literature, you know immediately that it is underpowered and that nonsignificant results have very little meaning. An astute reader should apply this type of reasoning to every manuscript. A well-written paper should discuss power and sample size so the reader does not have to fill in the blanks.

CONCLUSION

The medical literature is filled with examples of studies that did not enroll a sufficient number of subjects to provide an adequate test of key hypotheses. When sample sizes are inadequate, the power to detect between group differences is limited, and it may be impossible to determine if nonsignificant results really do mean that between-group differences are clinically unimportant. It is incumbent on both authors and readers to critically consider the impact of sample size and power on the interpretation of results.

Precision Medicine: Statistical Issues

Fuyu Song

Center for Food and Drug Inspection, China Food and Drug Administration, Beijing, China

Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

In clinical trials, a typical approach for the evaluation of safety and efficacy of a test treatment under investigation is to first test for the null hypothesis of no treatment difference in efficacy based on clinical data collected under a valid trial design. If significant, the investigator would reject the null hypothesis of no treatment difference and then conclude the alternative hypothesis that there is a difference in favor of the test treatment. If there is a sufficient power for correctly detecting a clinically meaningful difference (improvement) when such a difference truly exists, we claim that the test treatment is efficacious. The test treatment will then be reviewed and approved by the regulatory agency such as the United States Food and Drug Administration (FDA) if the test treatment is well tolerated and there appears to be no safety concerns. We will refer to medicine developed based on this typical approach as *traditional medicine*.

Keywords: Individualized medicine; Personalized medicine; Positive predictive value; Traditional Chinese medicine; Traditional medicine.

INTRODUCTION

In clinical trials, a typical approach for the clinical investigation of safety and efficacy of a test treatment is to first test for the null hypothesis that there is no clinically meaningful difference between treatments based on clinical data collected under a valid study design. If significant, the investigator would reject the null hypothesis of no treatment difference and then conclude the alternative hypothesis that there is a difference in favor of the test treatment. If there is a sufficient power for correctly detecting a clinically meaningful difference (improvement) when such a difference truly exists, we claim that the test treatment is efficacious. The test treatment will then be reviewed and approved by the regulatory agency such as the United States Food and Drug Administration (FDA) if the test treatment is well tolerated and there appears to be no safety concerns. We will refer to medicine developed based on this typical approach as *traditional medicine*.

In his State of the Union address in early 2015, President Barack Obama announced that he was launching the *Precision Medicine Initiative*—a bold new research effort to revolutionize how we improve health and treat disease. As indicated by President Obama, precision medicine is an innovative approach that takes into account individual differences in people's genes, environments, and lifestyles. Unlike traditional approach (traditional medicine), most medical treatments have been designed for the average patient. For this *one-size-fits-all* approach, treatments

can be very successful for some patients but not for others. Precision medicine, on the other hand, gives medical professionals the resources they need to target the specific treatments of the illnesses we encounter.^[1] In response to President Obama's Precision Medicine Initiative, the National Institutes of Health kicked off cohort grants for precision medicine to develop treatments tailored to an individual based on their genetics and other personal characteristics subsequently.^[2] Seeking for precision medicine of cure has become the center of clinical research in pharmaceutical development since then.

PRECISION MEDICINE

Unlike traditional medicine, precision medicine is referred to as a medical model that proposes the customization of health care, with medical decisions, practices, and/or products being tailored to the individual patient.^[3] In this model, diagnostic testing is often employed for selecting appropriate and optimal therapies based on the context of a patient's genetic content or other molecular or cellular analysis. Tools employed in precision medicine could include molecular diagnostics, imaging, and analytics/software. This has led to biomarker development in genomics studies for target clinical trial. A validated biomarker (diagnostic tool) is then used to identify patients who are most likely to respond to the test treatment under investigation in the enrichment process of the target clinical trials.^[4–7]

As a result, precision medicine will benefit the subgroup of patients who are biomarker positive. In practice, however, there may exist no perfect diagnostic tool for determining whether a given patient is with or without molecular target in the enrichment process of the target clinical trials. Possible misclassification, which could cause a significant bias in the assessment of treatment effect in target clinical trials, is probably the most challenging issue in precision medicine (see, e.g., the work of Chow and Song^[8]).

As an example, let Y_{ij} be the responses of the j th subject in the i th group, where $j = 1, \dots, n_i$; $i = T, C$. Y_{ij} are assumed approximately normality distributed with homogeneous variances between the test and control treatments. Also, let μ_{T+} , μ_{C+} , and (μ_{T-}, μ_{C-}) be the means of test and control groups for the patients with (without) the molecular target. Table 1 summarizes the population means by treatment and diagnosis.

In target clinical trials, it is of interest to estimate the treatment effect for the patients truly having the molecular target, i.e., $\theta = \mu_{T+} - \mu_{C+}$. However, this effect may be contaminated due to misclassification, i.e., for those subjects who do not have the molecular target but got positive diagnosed results and those subjects who have the molecular target but got negative diagnosed results. The following hypothesis for detecting a clinically meaningful treatment difference in the patient population truly with the molecular target is of interest:

$$H_0 : \mu_{T+} - \mu_{C+} = 0 \quad \text{versus} \quad H_a : \mu_{T+} - \mu_{C+} \neq 0 \quad (1)$$

Let $\bar{y}_T$ and $\bar{y}_C$ be the sample means of test and control treatments, respectively. Since no diagnostic test is perfect for the diagnosis of the molecular target of interest without error, therefore, some patients with a positive diagnostic result may in fact not have the molecular target. It follows that

$$E(\bar{y}_T - \bar{y}_C) = \gamma(\mu_{T+} - \mu_{C+}) + (1 - \gamma)(\mu_{T-} - \mu_{C-}) \quad (2)$$

where γ is the positive predicted value, which is often unknown. Thus, an accurate and reliable estimate of γ is the key to success of target clinical trials^[7] and hence precision medicine.

PRECISION MEDICINE VERSUS PERSONALIZED MEDICINE

The term *precision medicine* is often mixed up with the term *personalized medicine*. To distinguish the difference

between precision medicine and personalized (or individualized) medicine, the National Research Council indicates that precision medicine refers to the tailoring of medical treatment to the individual characteristics of each patient. It does not literally mean the creation of drugs or medical devices that are unique to a patient, but rather the ability to classify individuals into subpopulations that differ in their susceptibility to a particular disease, in the biology and/or prognosis of those diseases they may develop, or in their response to a specific treatment. In summary, precision medicine is to benefit the subgroup of patients with the diseases under study, whereas personalized medicine is to benefit individual subjects with the diseases under investigation.

Statistically, the term *precision* is usually referred to the degree of closeness of the observed data to the truth. High degree of closeness is an indication of high precision. Thus, precision is related to the variability associated with the observed data. In practice, the variability associated with observed data include (1) intra-subject variability, (2) intersubject variability, and (3) variability due to subject-by-treatment interaction. As a result, precision medicine can be viewed as the identification of subgroup population with larger effect size (i.e., smaller variability), assuming that the difference in mean responses is fixed. Consequently, precision medicine focuses on minimizing intersubject variability, whereas personalized medicine focuses on minimizing intra-subject variability. Table 2 provides a comparison between precision medicine and personalized medicine.

FUTURE PERSPECTIVES

As indicated earlier, traditional medicine can only benefit average patients with the diseases under study, whereas precision medicine can further benefit a subgroup of patients who have certain characteristics (e.g., molecular target). On the other hand, the ultimate goal of personalized (or individualized) medicine is seeking cure for individual patients if it is not impossible. President Obama's Precision Medicine Initiative is an important step moving away from the traditional medicine and toward precision medicine, then personalized (or individualized) medicine so that individual patients could be beneficial. For this purpose, traditional Chinese medicine, which often consists of multiple components and focuses on global dynamic harmony (or balance) within individual patients, is expected to be the center of personalized medicine development moving

Table 1 Population means by treatment and diagnosis

Positive diagnosis	True target condition	Indicator of diagnostic	Test group	Control group	Difference
+	+	γ	μ_{T+}	μ_{C+}	$\mu_{T+} - \mu_{C+}$
	−	$1 - \gamma$	μ_{T-}	μ_{C-}	$\mu_{T-} - \mu_{C-}$

Note: γ is the positive predicted value

Table 2 Precision medicine versus personalized medicine

Characteristic	Traditional medicine	Precision medicine	Personalized medicine ^a
Active ingredient	Single	Single	Multiple
Target population	Population	Population	Individuals
Primary focus	Mean	Intersubject variability	Intra-subject variability
Dose/regimen	Fixed	Fixed	Flexible
Beneficial	Average patient	Subgroup of patients	Individual patients
Statistical method	Hypotheses testing Confidence interval	Hypotheses testing Confidence interval	Hypotheses testing Confidence interval
Use of biomarker	No	Yes	Yes
Blinding	Yes	Yes	May be difficult
Objective	Accuracy	Accuracy Precision	Accuracy Precision Reproducibility
Study design	Parallel/crossover	Parallel/crossover Adaptive design	Parallel/crossover Adaptive design
Probability of success	Low	Mild to moderate	High

^aPersonalized medicine = individualized medicine

toward the next century.^[9] For achieving this ultimate goal, regulatory requirement and quantitative/statistical methods for the assessment of treatment effect for drug products with multiple components are necessarily developed.

Prediction Trees

Antonio Ciampi

McGill University, Montreal, Québec, Canada

Abstract

Prediction trees are powerful tools for extracting predictive information from data. This entry reviews different types of prediction trees while detailing the components of each type.

INTRODUCTION

Prediction trees are powerful tools for extracting predictive information from data. Their use is increasingly frequent in biomedical research, as in many other fields of application. The conceptual developments leading to the algorithms now in use concern many disciplines, statistics and machine learning among others. This article is written from a statistical perspective. In Statistics, one deals with variables measured on observational units. To formulate the prediction problem, one needs to distinguish between variables called predictors, and a (possibly multidimensional) variable of special interest called outcome. It is usually assumed that the expected value of the outcome μ is a function of the predictors' vector z : $\mu = \mu(z)$. A prediction rule associates to each possible value of the predictors, a characteristic of the probability distribution of the outcome, typically μ . The problem is to construct a prediction rule $\hat{\mu}(z)$ from a data matrix D , obtained from a series of observational units for which both predictors and outcome are known. The purpose of the construction is to be able to associate to new observational units, for which only the predictors are given, some reasonable guess about the outcome.

The analyst may decide to consider a particular functional form for $\mu(z)$, known except for a parameter of fixed dimensionality. The most popular examples of predictors defined this way are linear predictors: $\mu(z) = \beta z$ and generalized linear predictors:

$$h[\mu(z)] = \beta z$$

where h , the link function, is specified and β is a parameter. Then, the construction of the prediction rule from D reduces to the estimation of the parameter β . Alternatively, the analyst may choose to obtain a prediction rule through an algorithmic approach. In this case the function $\mu(z)$ is not specified through a parameter of fixed dimensionality, but through a series of algorithmic steps. The choice

between parametric and algorithmic approach is influenced by the current knowledge of the domain within which the prediction rule is needed. Ideally, a parametric approach should be based on a substantive theory justifying the chosen functional form, though, in actual applications, this is rarely the case. The algorithmic option is more appropriate in unstructured situations with limited theoretical knowledge. In these cases it would be highly desirable to propose algorithms that mimic cognitive strategies used by domain experts.

The construction of tree-structured predictors from data is algorithmic. The success of prediction trees may be partially explained by the fact that experts of many domains use some kind of recursive partitioning approach while making predictions. For instance, when making a prognosis, a physician may ask: "On the basis of my previous experience and knowledge, the most relevant prognostic characteristic is C_1 . Does this patient have C_1 ?" If the answer is yes, the physician may then make a prognosis. Or, if the information is not sufficient, the physician may evoke another prognostic characteristic, C_2 , say, as the most relevant prognostic information for patients having C_1 , and ask whether or not the patient has C_2 . Similarly, for patients not having C_1 , there may be another prognostic characteristic C_3 and a similar question: "Does this patient have C_3 ?" and so on. Clearly, this is an oversimplified model of the prognostic process, but it is a useful one for developing reasonable algorithms. Physicians are familiar with a graphic representation of this process, known as diagnostic key, or in the context of general medical decision, decision tree. It is tempting to say that the physician is actually applying a "virtual" prediction tree, which represents experience and knowledge. From the statistician's point of view, "experience and knowledge" have to be extracted from the data D . The challenge is to develop an algorithm that recursively searches for "most relevant predictors" and that also decides when to stop searching and actually predict. Thus, an algorithm for prediction tree construction must be based on a measure of "relevance" and a stopping rule.

BASIC NOTATIONS AND CONCEPTS

Fig. 1 represents a hypothetical prediction tree for predicting whether a cancer patient in remission will relapse within a year. It formalizes the process outlined above. The tree suggests asking a hierarchical set of questions about patients who belong to the population of interest. The presence of characteristic C_1 is ascertained for all patients. For patients with characteristic C_1 , one should ascertain the presence of C_3 , while for patients without C_1 , one should ascertain the presence of C_2 . The diagram implies that, on the basis of what is known at this stage (all measured variables), the prognostic process should be completed here. The labels at the nodes ($C_i?$) are called (binary) questions. By convention, circles represent points at which questions are asked. The top circle is termed root node or simply “root”; the other circles are termed internal nodes or, simply, nodes. Square boxes represent points at which predictions are made; they are termed terminal nodes or leaves. Circles and squares also represent subpopulations: For instance, the root node represents the general population and the left-most “leaf” represents the subpopulations of individuals with both C_1 and C_2 . Moreover, for a given data matrix D (a sample), nodes and leaves also represent sets of rows of D (subsamples). Graph theoretical language is also currently employed, but it hardly needs formal definitions. For instance, nodes issuing from the same “parent” node are known as its “children” and a subtree issuing from a node is a branch. Strictly speaking, the graph of Fig. 1 is a rooted binary “tree,” although tree is generally accepted.

Under the leaves, the probabilities of relapse within a year are reported. An alternative approach would be to indicate relapse or no relapse according to some decision rule, such as “if $p \geq 0.5$ then relapse,” “otherwise, no relapse.” Our preference is to express the leaf prediction as a probability, which is, indeed, the expected value of the underlying binary variable. In our case one can clearly see that the tree defines four prognostic groups: low, medium, medium-high, and high risk of relapse.

Fig. 1 Prediction tree for a binary outcome

PREDICTION TREES FOR A CLASS VARIABLE AND FOR A CONTINUOUS VARIABLE: CLASSIFICATION AND REGRESSION TREES

Tree-growing was introduced in the 1960s.^[1] The earliest algorithm was termed Automatic Interaction Detection. The goal was to predict a continuous univariate outcome, but extension to multivariate continuous outcome and categorical outcome was developed in the 1970s and early 1980s. The analog of the diagram of Fig. 1 would have, at each leaf, the conditional expectation of the outcome given the path joining the root to the leaf. The idea of the algorithm is extremely simple. At each node, the algorithm goes through all the predictors. For each value of a continuous predictor the data are split into subsets of cases above and below that value. For categorical predictors, the algorithm considers all binary groupings of its levels. The “goodness” of the split is assessed by a test statistic that compares the two subsets (t statistics, Hotelling’s T^2 , or chi-squared according to the type of outcome) and the “best split” is selected in consequence. The procedure is applied recursively to the subsets obtained by binary partitioning. The decision to stop branching is reached by assessing the “statistical significance” of the best split in the traditional sense. When no split is significant at some predetermined level the algorithm stops and the tree is obtained.

Until the mid-1980s, AID-like methods were used primarily in the social sciences and did not attract much attention within the statistical community. A change occurred, however, with the publication of the monograph *Classification and Regression Trees (CART)*.^[2] This seminal work formulated tree-growing within the framework of statistical learning theory, introducing ideas such as cross-validation and more general resampling schemes as reasonable remedies for the statistical problems implicit in intensive model searches. It developed a broad approach, known by its acronym CART, permitting the treatment of both categorical outcome (classification trees), and univariate continuous outcome (regression trees).

Recursive Partitioning in CART

The basic idea of the CART methodology is the separation of recursive partitioning from the choice of an optimal tree-structured predictor. We describe first the recursive partitioning phase. For a specified family of questions and a goodness of split measure, CART recursively partitions the root and children nodes by choosing at each node the question producing the best split. However, the stopping rule is not based on statistical significance, but rather on convenience considerations: In particular,^[2] propose to stop the recursive partitioning when the subsample of D at a node is too small, in a sense defined by the user, and/or, for classification trees, “pure,” i.e., consisting entirely of

elements of one class. Since statistical significance is not an issue, the choice of the goodness of split measure is now much broader. Moreover, the actual implementation of recursive partition may be governed entirely by computational efficiency requirements: For example, CART trees can be grown and stored by the efficient “depth first” strategy (add an extra split always at the leftmost node until no further split is possible). In contrast, earlier algorithms, and, indeed, some more recent ones, are “greedy” or best first algorithms: The current tree is updated by adding a split there where the best split is obtained.

For classification trees, one reasonable measure of goodness of split is based on the notion of node impurity, a quantity that assesses departure from a pure node. The impurity at a node t , $i(p|t)$, is indeed a function of the probability distribution of the outcome variable, $p = \{p(j|t); j = 1, 2, \dots, J\}$ which measures the “spread” of the distribution of the outcome: The more “peaked” the distribution, the smaller the impurity, with impurity zero associated to the case where one class is observed with probability 1 and the others are observed with probability 0 (pure node). The class probability distribution at node t , $p = \{p(j|t); j = 1, 2, \dots, J\}$, is generally unknown and has to be estimated from the data. Strictly speaking, we work with “estimates” of impurity $\hat{i} = i(\hat{p} | t)$. Several choices of impurity measures have been used, the most popular ones being Shannon’s entropy, and the Gini index. The definition is naturally extended to a split: The impurity of a split is the weighted sum of the impurities of the children nodes with weights given by the relative frequency of the children’s population sizes. Then, the impurity reduction due to the split (see CART for exact definitions) appears as a reasonable candidate for measuring goodness of split. One interesting property of impurity reduction is that it can be easily generalized to any partition, hence to the partition generated by a tree. In CART, the Gini index is recommended as an impurity measure; however, the authors also propose another measure of goodness of split, twoing, which does not have the properties of an impurity measure.

For regression trees, there is a natural measure of impurity at a node: the mean squared deviation from the mean of the continuous outcome, estimated on the subsample represented by the node. Impurity reduction due to a split (partition and tree) is defined accordingly. With this definition, regression tree-growing is seen as an adaptive least square regression algorithm—adaptive in the sense that binary variables are constructed from the original predictors as the algorithm unfolds. An alternative, equally natural definition of impurity at a node is the mean absolute deviation (MAD); with this choice tree-growing is an adaptive MAD regression algorithm.

Pruning in CART

The tree obtained in the recursive partitioning phase is termed large tree. It may be expected that the large tree

overfit the data. In other words, the predictive relationships between predictors and outcome suggested by the large tree reflect accidental properties of the data matrix D , which do not necessarily hold in the population from which D has been drawn. The optimal tree-structured predictor, or honest tree (honest because less prone to overfitting) is then selected among all the subtrees containing the root of the large tree. Following the tree metaphor, this second phase is termed “pruning”; in particular, the procedure proposed in CART is known as cost-complexity pruning. It is an algorithm that selects the honest tree by minimizing an appropriate cost-complexity function.

To define a cost-complexity function, one needs:

- A measure of cost associated to a predictor, which is smaller the more accurate the predictor. Cost must be a function of the tree structure T and of the data matrix D : $R(T, D)$; more specifically, cost depends on D through the estimates of $\mu(z)$ based on D . It would be tempting to identify $R(T, D)$ with the impurity reduction due to T . Indeed, CART adopts this definition for regression trees; however, for classification trees, the CART authors argue in favor of choosing for $R(T, D)$ the resubstitution–misclassification risk, which reduces to the resubstitution–misclassification error when all errors have the same cost. Resubstitution refers to the fact that these quantities are calculated on the same data set D used for the tree construction: It is a biased estimate of the true quantity.
- A measure of complexity associated to the tree structure, $g(T)$, and not depending on the data. Classification and regression trees define complexity as the number of terminal nodes of the tree.
- A complexity parameter α is a tuning parameter that has to be adjusted from the data through cross-validation, as we shall see later.

Then, the cost complexity of a tree T obtained from the data D is

$$CC_\alpha = R(T, D) + \alpha g(T)$$

Clearly, it is a linear combination of the cost and the complexity of a tree with the complexity parameter defining the tradeoff between the two. For $\alpha = 0$, only cost is important, and the large tree is the best tree. As α increases, complexity overrides cost and the best tree is eventually the trivial tree.

It can be shown that for a fixed α there is a unique subtree T_α of the large tree which minimizes cost complexity. In fact, one can construct a finite increasing sequence of α values associated to distinct subtrees:

$$T_{\text{large}} \supset T_{\alpha_1} \supset T_{\alpha_2} \supset \dots \supset T_{\alpha_{\max}} = \{\text{root}\}$$

This is known as the pruning sequence: It is uniquely associated to the data set D . Clearly, any tree of the pruning sequence is a honest tree for some values of α . Thus, to complete pruning, an algorithm to choose α is needed.

How should the complexity parameter be determined? We have already remarked that $R(T, D)$ is a biased estimate of a theoretical quantity—it is usually smaller than its true value, so that several authors call the bias optimism and describe the bias as optimistic. Now, if we have another set of independent data D^* from the same population as D , we could use the parameters estimated on D to calculate the cost function on D^* . The cost $R(T, D; D^*)$ estimated this way is less optimistic than $R(T, D)$. Ideally, it would be desirable to have a sequence of new independent data sets $D^{*(i)}, i = 1, 2, \dots, B$. Then, one would obtain an even better estimate of true cost by computing the average of the $R(T, D; D^{*(i)})$'s, $\bar{R}^B(T)$, with the associated standard error providing a rough measure of the variation of the estimate. Then a very reasonable choice of α would be the value α^* such that $\bar{R}^B(T_{\alpha^*})$ is minimum.

Since such a sequence of independent data sets is rarely available, the CART monograph proposes to determine α^* by a resampling scheme such as cross-validation or the bootstrap. They opt for a particular kind of cross-validation, termed V -fold cross-validation. The original data matrix D is divided into V approximately equal parts, $D^{(v)}, v = 1, \dots, V$. For each v , a tree is grown on $D/D^{(v)}$, a pruning sequence is obtained from the α 's defined on the large tree, and costs are evaluated on $D^{(v)}$ for each α . For each α , one obtains V costs, which are averaged to obtain $\bar{R}^V(T_{\alpha})$; then α^* is chosen as the value for which $\bar{R}^V(T_{\alpha^*})$ is minimum. We refer to the CART monograph for a thorough presentation and an alternative selection rule which relies also on the standard errors of the $\bar{R}^V(T_{\alpha})$'s.^[2]

Notice that the CART pruning algorithm grows $V + 1$ large trees and pruning sequences. Indeed, there is no reason to expect that distinct $D^{(v)}$ gives rise to the same large tree and pruning sequence. On the other hand, the honest tree is selected from the pruning sequence of the large tree obtained from data matrix D ; the other large trees remain “invisible” to the analyst.

Other Algorithms for Constructing CART

There is a large family of algorithms that attempts to improve on CART. Here, we will discuss work aimed at improving the accuracy of prediction. The elements of the CART algorithm that can be changed to improve predictive accuracy are mainly the search for the best split at a node and the approach to the selection of the honest tree.

One of the shortcomings of CART methodology affecting prediction accuracy is the bias inherent in split selection: Since a split is chosen by extensive searches, predictors with many levels are favored and tend to appear more often than they should in the large tree. To reduce this bias Loh and Vanichsetakul proposed the algorithm FACT

for classification trees.^[3] The authors separate the problem of variable selection from that of split selection. By performing a discriminant analysis at each node for each predictor, they select first one predictor, and then split on the selected predictor. The discriminant analysis approach, naturally leads to a multiway split. FACT also avoids the CART-style pruning approach, but uses a node-based stopping rule. A later development led to the algorithm QUEST, which yields binary trees and allows pruning as an option.^[4] FACT and QUEST reduce the bias in favor of predictors with many levels. Moreover, QUEST was shown to produce the best predictive accuracy among 33 “old and new classification algorithms.”^[5] The algorithm GUIDE extends the split selection approach to the case of regression trees.^[6]

Prediction accuracy can also be improved by merging nodes from different parents, if appropriate. This can be done by amalgamating leaves of the honest tree or during the process of tree construction.^[7–9] The resulting structure, however, is no longer a tree in the strict sense, but an “induction graph.”

GENERALIZED PREDICTION TREES

We have described so far CART and the elements of their construction. Several generalizations have been proposed with two distinct purposes:

1. Improving prediction accuracy.
2. Predicting aspects of the distribution of the outcome other than its expected value. In particular, this is useful when working with an outcome that is more complex than a categorical outcome or a one-dimensional continuous outcome.

One way to improve prediction further is to adopt predictive structures more general than a tree. On the other hand, one can build predictors for other aspects of the distribution while preserving the basic tree structure.

The approach proposed aims at both purposes.^[8,10] The key idea is to explicitly assume that the purpose of the prediction is to associate to a set of the predictor variables an aspect of the outcome distribution represented by a parameter θ that does not necessarily determine the distribution completely. To determine the distribution completely one needs (θ, ψ) , where ψ can be seen as a “nuisance” parameter to be treated in an appropriate way. The parameter of interest may also be affected linearly by other covariates, x , say, termed leaf variables (criterion variables in earlier versions). The nuisance parameter may also depend on other covariates, and the RECPAM algorithm distinguishes between root and virtual variables (global and local variables in an earlier version). Without entering in the details we will simply state here that this idea gives rise to an “enriched” tree structure.^[8,10] A generalized RECPAM

tree is indeed a tree, possibly with partially merged leaves; however, the prediction at the leaves occur through a regression equation containing the leaf variables, possibly supplemented by an additional root regression equation, the coefficients of which do not vary across leaves. Another important feature of RECPAM methodology is the replacement of the notion of impurity at a node with that of generalized information, basically a “badness of fit measure” that compares the estimated parameter θ with the data. In most cases developed so far, the badness of fit measure is the deviance or some quantity with properties similar to those of the likelihood—which justifies the term “information.” Then, one can easily define quantities, such as generalized information gain (corresponding to “impurity reduction” of CART) and information loss, which are at the heart of the RECPAM algorithm. In the standard cases of classification and regression trees and in many other examples, these quantities correspond to likelihood ratio statistics.

Tree-Structured Classification and Regression

The idea of “adding regression equations” to a tree structure, termed tree-structured regression or treed regression, has been independently pursued by other authors.^[11–13]

The RECPAM approach contains essentially the tree-structured models described above. Its main limitation is that the analyst has to specify a priori which variables are predictors, leaf, virtual, and root. This may be possible in highly structured problems with rich peripheral knowledge. For example, one may be interested in comparing the effect of two treatments as a function of specified variables (effect modifiers)—in other words, one wishes to assess the potential interactions between treatment and other covariates. Then, one simply specifies the binary treatment variable as leaf, the constant term as a nuisance parameter to be treated as a virtual variable, and all other variables as predictors. On the other hand, in unstructured problems such as those occurring in a data mining context, it is hard to decide which variables enter the linear predictors. When in doubt one can require that all variables are leaf variables, as some of the above-cited authors do. However, if only a few predictors are truly needed at each leaf, this option will be too noisy and will result in prediction inaccuracy. Therefore, it is highly desirable to reduce noise by automatic selection of the variables entering each of the regression equations at the leaves. This was achieved by Chaudhuri et al. and Kim and Loh, who proposed accurate and computationally efficient algorithms for tree-structured classification and regression.^[12,13]

Trees for More General Outcomes

Biomedical studies are increasingly based on more complex outcomes than a class variable or a single continuous variable. Count data occur, for instance, in the study of disease distribution, and they are treated through Poisson regression

or generalizations thereof (negative binomial regression or partially specified regression with parameter estimation based on quasi-likelihood). Survival outcomes with censoring have been common in clinical biostatistics for quite some time, and they have stimulated the development of a large family of regression models, among which the Cox model continues to occupy a central place. More recently, event history data have become increasingly common to describe the evolution of chronic diseases with recurrent acute phases. Repeated measurements of continuous, binary, or categorical variables and, more generally, clustered measurements such as those that occur in meta-analysis and in multilevel systems, are now active areas of methodological and applied statistical research. The interest often centers on assessing the effect of some covariates on outcome: linear regression of some kind (regression for correlated continuous or discrete outcome, event history regression, multilevel regression, etc.) is usually the first tool on which the analyst relies. When a full statistical model is available for the regression model, likelihood-based estimation of the parameters is most commonly used, as, for example, in mixed models for continuous outcomes. When only a portion of the statistical model can be specified, the likelihood is replaced by closely related quantities, such as a partial likelihood (Cox regression and its generalization for repeated events), quasi-likelihood (regression for categorical and count correlated data), etc. It is natural to develop tree-based methods as an alternative to or complement of nonstandard regression models and this has been done successfully for some situations.

The RECPAM approach, with its reliance on likelihood-based measures of information gain, offers a natural framework for converting a given linear regression model into a tree-growing algorithm, and indeed into a tree-structured regression model.^[8] The RECPAM approach has been developed for the generalized linear model, which includes, among others, trees for binary, Poisson (possibly with overdispersion), and censored exponential outcomes, and for the Cox model.^[7,14] The RECPAM algorithms based on the Cox model contain the unique feature of tree-structured subgroup analysis: a tree can be grown to predict differential treatment effects from predictors, while correcting for the possible direct effect of predictors on survival. RECPAM tree-growing algorithms, treed regression, and subgroup analysis have also been proposed for multivariate normal outcomes.^[15]

The limitation of the actually developed algorithms of the RECPAM family is that they are not always optimized for predictive accuracy and computational efficiency and further work is needed in most cases to improve on these features. On the other hand, there are very accurate and efficient algorithms that, while less general than RECPAM and based on different approaches, achieve similar purposes extremely well. See, for example, the tree-structured Cox regression algorithm proposed by Ciampi and Loh for survival outcome and the treed generalized regression algorithm of Chaudhuri et al.^[12,16,17]

Fig. 2 Prediction tree for survival curves: melanoma data

Other approaches to tree-growing for survival outcome have been developed.^[18–23] Prediction trees for longitudinal outcomes have also been independently proposed by Segal.^[24] A tree-growing algorithm and treed regression for binary correlated outcomes has been developed by Ann and Chen.^[25] We refer to Zhang et al. for an excellent review of the use of trees in the health sciences and interesting original contributions.^[26]

To conclude this section, a prediction tree for survival curves, constructed from real data, is presented in Fig. 2. The data, included with S-plus 6.2, as data frame Melanoma, were collected on patients with malignant melanoma at Odense University Hospital, Denmark, by K.T. Drzewiecki. The outcome is censored survival time and the prognostic variables include sex, age, tumor thickness (in mm), and ulceration (a binary variable denoting the presence or absence of ulceration). The tree was constructed using the generalized linear model module of RECPAM, under the hypothesis of exponential survival times conditional on the covariates. This tree structure has five clearly identifiable leaves, which after the amalgamation step, yield three distinct prognostic groups (RECPAM classes). The survival curves of the prognostic group are also shown in the graph. It is easy to read off the graph the definition of each prognostic group, and to visualize the corresponding survival curve. Clearly, the “best prognosis” group comprises patients younger than 65, without ulceration and with a tumor thickness less than 0.65 mm; the “worst prognosis” group consists of patients with ulceration and tumor thickness greater than 3.22 mm; the remaining patients constitute an “intermediate prognosis” group.

SOME DIRECTION OF CURRENT RESEARCH

We have described a basic structure—a tree—possibly with equations at some leaves and some merger of nodes or

leaves and we have summarized a number of approaches to extract such a structure from data. Although minor improvements are still possible within the basic construction process, some of the most promising ongoing research is aimed at extending the basic model further. More general structures and constructive algorithms to extract them from data have been proposed. In general, the new structures lose some interpretability in exchange for better predictive accuracy.

Trees with Soft Nodes

One recent proposal is that of a tree with soft nodes.^[27] The idea is very simple and it applies to splits on continuous predictors. Consider, for example, a split on the variable age. It seems interesting to replace a question of the type: “Is the subject older than 60?” with “Is the subject old?” Since “being old” is not a sharply defined concept, one can interpret the question as “Should the subject be considered old and with what probability?” A “soft split” as in Fig. 3, therefore, replaces a “hard split,” where the sigmoid curve gives the probability of “going left.” A hard node then can be seen as a limiting case of a sigmoid curve that becomes a “step function.”

An algorithm to construct a soft tree to predict binary variables has been developed and empirical evidence shows that it produces generally better predictions than a hard tree. Work is in progress to extend the algorithm to continuous and categorical variables. The soft tree is strongly related to a much more general structure, a hierarchy of expert, proposed as a hybrid neural network in the literature of machine learning.^[28] In such a hierarchy, leaves are seen as low-level experts, and nodes are “superexperts” who make predictions by weighting the decision of their immediately subordinate lower-level experts (children, in tree language). In the general context, weighting is represented by a neural network or a linear combination of predictors, which results in a marked

Fig. 3 Prediction tree with soft nodes for a binary outcome (From Ref. [27]; p. 1154.)

loss of interpretability. The tree with soft nodes reintroduces interpretability, by replacing neural nets with soft splits on a single variable. Moreover, while a hierarchy of experts is based on a prespecified number of experts disposed in a predefined hierarchical structure, the tree with soft nodes is entirely constructive in that it extracts from data both the hierarchical structure and the form of the soft splits.

Forests and Bayesian Trees

A completely different direction is being explored.^[29–31] We have already remarked at the end of the section Pruning in CART that the cross-validation algorithm involves the construction of several “large trees,” which are used in a very limited way and only as a means to choose a subtree of the main large tree. The main idea behind a variety of approaches is to use more than one tree as a predictor: This multiplicity of trees is sometimes called a forest. The problem of combing different trees has given rise to several algorithms such as “bagging,” “arcing,” and others.^[32] Gains in predictive accuracy are impressive, but the analyst has to give up the simple, easily interpretable single-tree predictor; instead, the concept of forest and averaging has to be explained to the nonstatistician expert, rarely an easy task.

There is another idea leading also to forests: Bayesian trees.^[33–35] In the Bayesian inferential paradigm, one needs

to specify priors on the space of all trees. Given the data, a family of models and some heuristics, one obtains a posterior probability on the space of all trees, which of course can be seen as a forest. In principle, a Bayesian prediction is obtained by averaging predictions from all possible trees using the posterior distribution. In practice, one reports the tree with the highest posterior probability and a few “meaningful” trees of posterior probability close to the maximum. In a way, Bayesian trees offer a principled approach to tree averaging within Bayesian inference. Bayesian trees, though very promising, need much further exploration. One of the main obstacles to more extensive use so far is scalability of the basic algorithms: It is not clear to what extent these algorithms work in reasonable time on massive data sets.

Predictive Clustering

While trees occupy an important position in supervised learning, they are beginning to appear also as a tool in unsupervised learning. The idea proposed is a new development of two earlier approaches.^[36–39] One can state the problem of clustering within a prediction framework as follows: given a vector of variables x , determine a partition of its components: $x = (y|z)$ such that z optimally predicts (in some sense) y . For example, one can require that the components of y be conditionally independent given z .

CONCLUSIONS

As we have seen, research on prediction trees is an extremely fertile area. Not only are very useful predictive tools now available, but also new tools are being developed constantly. By their nature, prediction trees continue to attract the attention of several communities of researchers: among others, the statistical community and the machine learning community. Indeed, one of the most promising trends in ongoing research is the convergence of independently developed traditions from different communities. Integration of computer science and statistical expertise, which has already proved extremely fruitful, will hopefully continue. Some advances will only be possible through a multidisciplinary combination of efforts: this is necessary to meet the challenges and opportunities arising from the need of tackling poorly structured prediction problems suggested by the availability of massive data sets.

Premarket Applications: Registries

Nelson Lu, Yunling Xu, and Lilly Q. Yue

Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

National and international registries provide real-world evidence and can be used to potentially reduce the cost of clinical trials. These registries are playing a more and more important role in assessing the risk and benefit of medical devices. In this entry, related statistical and regulatory challenges and opportunities when utilizing registry data are discussed in detail from the following aspects: (1) adequacy of registry data quality; (2) bias introduced at every stage and aspect of study when incorporating registry data; (3) scientific validity of the study design; and (4) reliability and interpretability of the study results.

Keywords: Medical device; Registry; Data quality; Observational comparative studies; Study design; Propensity score.

INTRODUCTION

It is well perceived that randomized controlled trials (RCTs) provide the highest level of evidence in evaluating medical products, if they are designed and conducted properly. Sometimes for medical device clinical studies, conducting an RCT is not feasible due to ethical or practical issues, or a less burdensome approach is sufficient to provide the valid scientific evidence needed to support a marketing application.^[1] As a result, alternate study designs may be considered, including observational (non-randomized) clinical studies, to support medical device premarket applications.

Although RCTs have many advantages, they certainly have limitations. They require greater cost and time, and the generalizability of clinical findings to real-world medical practice may be limited, given the strict enrollment criteria that are typical in RCTs. Therefore, there has been increasing interest in expanding and integrating clinical research into more real-world settings and in utilizing real-world “big data” such as high-quality national or international registries.

A patient registry is an organized system using observational study methods to collect uniform clinical and other data to evaluate specified outcomes for a population defined by a particular disease, condition, or exposure, and it serves one or more predetermined scientific, clinical, or policy purposes. A registry database is a file (or files) derived from the registry. Furthermore, registries are classified according to how their populations are defined. For example, product registries include patients exposed to biopharmaceutical products or medical devices; disease or condition registries are defined by patients having the same diagnosis.^[2]

The use of registry data has been explored for premarket regulatory decision-making for some medical devices. Here are some of such examples. The Interagency Registry for Mechanically Assisted Circulatory Support has been used to form a control group in the evaluation of a new ventricular assist system. Similarly, control groups have been formed from registries such as Extracorporeal Life Support Organization and the Vascular Quality Initiative. United Network for Organ Sharing (UNOS) registry data have been employed to supplement the clinical data collected in an RCT for the evaluation of an investigational device. The analysis of long-term survival data in UNOS provided great assistance in regulatory decision-making. To investigate an alternative access approach for transcatheter aortic valve replacement in inoperable patients with aortic stenosis, a study embedded in transcatheter valve therapy registry was designed.

In the following sections, related statistical and regulatory challenges and opportunities for utilizing registries for confirmatory medical device studies are discussed in detail.

POTENTIAL OPPORTUNITIES

For a well-established device technology and medical practice, a well-designed and executed national or international registry has the potential to: (1) complement the knowledge obtained from “traditional” clinical trials to answer scientific and clinical questions; (2) support applications, including therapeutic development, outcome research, patient care, quality improvement, medical product surveillance, and well-controlled effectiveness studies; and (3) allow researchers to answer health-care questions

efficiently, with savings in both time and cost, and for broader patient populations.^[3]

Some opportunities in the use of registry data exist for pivotal confirmatory medical device studies. The information obtained from a registry may generate a hypothesis to be tested in confirmatory clinical studies. Registry information may serve as supplementary data and provide additional information. For certain types of medical devices, the registry data may be used to derive a performance goal or objective performance criteria, which can be used in a single-arm clinical study.

Another usage of registry data is to form a control group (with patient-level data available) to serve as a compactor to the investigational device. Statistical methodology and considerations are extensively discussed in this entry. It is possible that a prospective clinical study can be embedded within a registry. In such a case, the statistical methodology used in traditional clinical trials is applicable.

For an existing approved medical device, the information from real-world use may be captured in some registries. Such information may be utilized to provide evidence for labeling updates or labeling extensions, such as expanded indications and expanded patient populations.

GENERAL CONSIDERATIONS

A registry needs to possess certain features in order to be utilized in the evaluation of confirmatory medical device studies.^[4] The discussion here focuses on the statistical and study design issues only.

Data Quality and Relevance

To obtain sound scientific evidence from a study, it is essential to have data with high quality. It is certainly true for evidence generated from registry data as well. The data quality of registries varies widely due to factors such as the purpose of the registry, carefulness in designing phase, various practical constraints, adequacy of site training, data handling, etc. To serve as the primary data source used to evaluate the risk and benefit of a medical device, it is important that the registry data have adequate quality to generate valid scientific evidence.

Important factors that need to be assessed include the relevance and reliability of the registry. They are extensively discussed in the U.S. Food and Drug Administration (FDA) Draft Guidance “Use of real-world evidence to support regulatory decision making for medical devices.”^[4] Please note that the Draft Guidance documents represent FDA’s thinking, but are not implemented until being finalized. Relevance indicates that the registry data can adequately address the applicable regulatory question or requirement. Ideally, the overall assessment of relevance would conclude that the existing observational data source is reliable, complete, consistent, accurate, and contains all

critical data elements necessary for evaluating the performance of a device in the applied regulatory context. Important factors for assessing the reliability of registry data include how the data were collected (data accrual), whether the data as collected are complete, accurate, and adequate for answering the question in hand (data adequacy), and whether the people and processes in place during data collection and analysis provide adequate assurance that bias is minimized and data quality and integrity are sufficient (data assurance).

Good practice to ensure high data quality in a well-conducted clinical study is important in registries as well. Some practices to enhance the relevance and reliability of a registry database are as follows: (1) accurately collect and record data; (2) adequately monitor the registry study to maintain the data integrity; (3) collect relevant information, including all key baseline covariates and clinical outcomes in the registry; (4) minimize missing data in baseline covariates and number of patients not completing the endpoint evaluation; and (5) utilize mechanisms such as central clinical event committees and core labs to reduce bias and variability of the study.^[5]

Registry versus Clinical Study

Device registries reflect the product use in the real-world. A wider patient population is generally expected in a registry, compared to a clinical study with defined inclusion/exclusion criteria. In addition, the skill levels and experience of the physicians are more varied in the real-world setting than in a clinical trial setting as well as the levels of ancillary care. Patients are treated under less-controlled environment in the real-world as there are usually no clinical protocols, and practices may vary among sites/physicians.

When it is intended to compare results of a clinical study with results of control groups formed from a registry database, careful considerations are needed. For a registry to serve as an acceptable data source, it needs to be relevant in terms of the ability to adequately address the applicable clinical questions under consideration. The clinical comparability between the registry database and the investigational study needs to be demonstrated with respect to patient population, treatment management, patient follow-up, definition of endpoints, the clinical event adjudication, etc.

It is important to assess whether clinical outcomes are affected due to different features between a registry and a well-conducted clinical study. In some cases, the clinical performance exhibited in a clinical trial tends to be better than that exhibited in a registry. Such situations may arise as, for example, patients in clinical studies are more likely to receive optimal medical treatment and/or guideline-recommended care. This could have important ramifications when the registry data are used as a comparative control, as the treatment effect of the investigational

device relative to the control is likely to be overestimated. In some situations, it is possible that the clinical events of subjects in a registry are less likely to be detected than subjects in a clinical trial. Note that oftentimes these features may be difficult to be captured in registries, and therefore such bias issues cannot be properly addressed via any statistical methodology.

CONTROL FORMED FROM REGISTRIES

One of the uses of registry data in the confirmatory medical device evaluation is to form a control group to serve as a comparator to the investigational device. For this purpose, the registry is not limited to a device registry and it could be a device, medication, surgery, etc. Appropriate registry selection, careful study design and planning, and pertinent statistical methodology are of paramount importance for reaching a valid comparative conclusion.

In selection of an appropriate registry, points discussed in section “General Considerations” need to be considered. The comparability between treatment groups is critical. Bias may be introduced from a lack of comparability. It is possible that treatment effect is confounded with time due to evolution of medical technology, learning effect of device use, changes in patient population, etc. Such a concern may be alleviated if there is sufficient overlap in the time frames between the investigational study and registry. If treatment effects are expected to be different among regions, the regions of a registry are better to be matched with where the investigational study is conducted.

In an RCT, the distributions of all observed and unobserved baseline covariates are expected to be balanced between two treatment groups. However, the same cannot be expected in an observational study as the treatment selection and study outcomes could be influenced by subject baseline characteristics. Without proper adjustment, great bias may be presented in the treatment effect estimates. A commonly used approach to reduce the bias is propensity score methodology, which was introduced by Rosenbaum and Rubin.^{[6][7]} The propensity score is the probability of treatment assignment conditional on observed baseline characteristics. Propensity scores are often estimated using a logistic regression model, with the treatment assignment as the dependent variable and baseline covariates as independent variables. With the estimated propensity scores, further design and analysis can be performed. One commonly adopted method in confirmatory medical device studies is to stratify subjects into groups (of roughly equal sizes) with similar propensity scores. Another method is to match each subject in the investigational device group with a unique control subject with a similar propensity score.

One critical feature of an RCT is that the study is prospectively designed. Naturally, an RCT is designed without access to any outcome data from either treatment groups.

This ensures convincing and interpretable treatment comparison results regarding outcomes. Such a feature is critical to be maintained in confirmatory, comparative observational studies under the regulatory setting. Without proper effort, the data can be analyzed with outcome data in sight. The objectivity and validity of the study design and the interpretability of the study results can greatly suffer. As pointed out by Rubin,^[8] “it is essentially impossible to be objective when a variety of analyses are being done, each producing an answer, favorable, neutral, or unfavorable to the investigator’s interests.” To address this issue, Yue, Lu, and Xu^[5] proposes a two-stage study design process.

The first design stage occurs before the initiation of the investigational study. In this stage, the preliminary sample size of the investigational device study is determined. An independent statistician is identified to perform the propensity score estimation and design. Masking mechanisms, such as a firewall, are planned to control access to any outcome data from this independent statistician during the entire design process. The patients’ baseline covariates to be collected and included in the propensity score modeling are specified.

The second design stage is conducted once the subject enrollment is completed and baseline covariates data are available. The previously identified independent statistician performs the task of estimating the propensity scores, grouping subjects based on the propensity scores, and assessing the covariate balance. An iterative process is usually taken until the covariate balance is reached. The statistical analysis plan is finalized at this stage. In the entire process, only the treatment assignment and baseline covariates data are needed. Any clinical outcome data and follow-up information are not needed nor are accessed.

The following lists some practical issues in implementing this practice.

Covariate Selection

In the first design stage, one task is to identify all covariates that are to be collected in the clinical study, included in the propensity score estimation model, and checked with balance between treatment and control groups. As reducing bias is an important task from the regulatory perspective, the list of covariates is usually prespecified to serve this objective. When a covariate that is related to both treatment assignment and outcomes is missing from the propensity score model, one of the key assumptions in propensity score methodology, ignorable treatment assignment assumption, may not be fulfilled.^[9,10] To reduce the possibility of such a scenario, a good practice is to include as many covariates in the list as possible (refer to the study by Yue, Lu, and Xu^[5] for more discussion).

Based on this principle, one of the key criteria to select a registry is that the information of all known important confounders is collected in the registry.

Missing Data in Covariates

In practice, it is common that there is a substantial amount of missing values in some of the covariates. If the analyses are performed based on data, excluding subjects with missing covariates, sample size is reduced and, more importantly, study conclusion may be questionable. Therefore, imputation of missing data is usually performed. For example, commonly used multiple imputation method or some adaptations thereof may be adopted (refer, for e.g., the study by Qu and Lipkovich^[11] for discussions). Simulation study results are presented in Mitra and Reiter^[12] to compare two approaches of estimating propensity scores after multiple imputation of missing covariates value.

Covariate Balance Diagnosis

In the propensity score adjusted analysis, inferences on treatment effect are valid only if covariates are balanced based on the selected propensity score design.^[6,13,14] Therefore, it is important to demonstrate the balance of baseline characteristics for the design based on the estimated propensity scores.

If the balance is not reached, alternative propensity score estimation modeling or a complete redesign of the control group may need to be performed. An iterative process between propensity score estimation/design and covariate balance assessment may be needed to finalize the propensity score estimation and design.

To demonstrate the balance of baseline characteristics, the common practice is to assess the marginal distribution of every observed covariate that is identified in the first stage design. Some appropriate methods include the graphical presentation and numerical quantities such as standardized (absolute) mean difference and variance ratios.^[14,15] The application of standardized (absolute) mean difference when it is utilized under propensity score stratification technique is discussed in the studies by Yue et al.^[3,5] and Li et al.^[16]

Selection of Subjects from Registry

It is important that the analysis set is specified in the second design stage. In an observational comparative study, oftentimes not all subjects from two treatment groups are comparable in terms of the distribution of propensity scores. In the practice, some subjects from one or both groups are removed to obtain better matches. While such a practice is common and well accepted in general research, it may be problematic in the confirmatory medical device studies. Discarding subjects in the investigational device can alter the intended population and make the resulting population difficult to be defined for labeling. Because of this regulatory constraint, it is important that the range of propensity scores for control group should cover the range of the subjects treated with the investigational device.

Sample Size and Power

The preliminary sample size is planned in the first design stage. The planning could be fairly challenging, and careful consideration may be demanded due to some uncertainties. The major challenge is due to the uncertainty regarding the degree of comparability in subjects' characteristics between both groups. Poorer comparability may result in the requirement of a larger sample size to achieve a certain power. Even if the number of subjects in the registry appears to be abundant, it is possible that the number of subjects that are comparable to the subjects in the investigational device group with respect to patient characteristics is much smaller.

When a control group is formed from a registry that is ongoing at the same time as the clinical study, the number of patients in the registry is unknown at the design stage. This may add even more complexity in the sample size planning.

To deal with these uncertainties, it may be better to take a more conservative approach. A larger sample size may be desirable in order to safeguard against the (unexpected) poor comparability and allow for greater flexibility in the second design stage.

CONCLUSION

National and international registries provide real-world evidence and can potentially be used to reduce the cost of clinical trials. To complement the major role of RCTs, these registries can play an important role in assessing the risk and benefit of medical devices in confirmatory studies. The key is to appropriately address statistical and regulatory challenges through the following actions: (1) ensuring the adequacy of data quality and (2) minimizing potential bias via scientifically valid study designs and proper statistical methods. By doing so, the study results could be reliable and interpretable, and the evidence may be generated to support regulatory decisions.

Principal Component Analysis

Aiyi Liu and Enrique F. Schisterman

National Institute of Child Health and Human Development, Bethesda, Maryland, U.S.A.

Abstract

Principal components are obtained through a series of variance maximization of the linear functions of the original variables. This entry discusses the concepts, analysis, and some biomedical applications of principal components.

INTRODUCTION

This article discusses the concepts, analysis, and some biomedical applications of principal components. Originated by Pearson^[1] and later formalized by Hotelling,^[2] principal component analysis has become one of the best known techniques of exploratory multivariate data analysis and has found applications in many areas of scientific research. It is a topic that appears in almost every textbook on multivariate data analysis^[3–5] and is the main focus of several technical books.^[5–8] In the past several years, the widespread interest among medical researchers in microarray experiments and gene expression analyses, a rapidly growing technology in human genome studies,^[9,10] has become one of the few new forces that further vitalize this decades-old topic.^[11–15]

Although useful in practice, the aim of principal component analysis is somewhat simple: to reduce data dimensionality while retaining as much as possible the variation among the data. In doing so, the method linearly transforms a large number of intercorrelated variables, often referred to as the original variables, into the same or fewer number of uncorrelated variables, each called a principal component, in a way that the variances of these components are in descending order, so that the first several principal components explain most of the variation among the original variables. Selected according to a prespecified cut point of percentage of total variation explained, or some other criteria, these leading principal components contain all (or most of) the information inherent in the data and hence determine the dimensionality of the data; the remaining components are considered to be noise and contain little information about the data. Data analyses based on these leading principal components are then performed instead of analyses based on the original variables.

In addition to dimensionality reduction, principal component analysis has been shown to be a useful tool in other data analyses such as extracting information, seeking important regressors in regression analysis, and effectively visualizing and clustering subjects. In principle, any data

analyses can be conducted in a low-dimensional variable space based on the selected leading principal components, instead of a high-dimensional variable space with the original variables. However, for the analysis to be efficient and its results reliably interpreted, principal components being selected must retain, to a satisfactory extent, the information contained in the original variables.

PRINCIPAL COMPONENTS

The simplest way to present principal components is perhaps the one using matrix notations.^[4] Let $\mathbf{x} = (x_1, \dots, x_p)'$ be a p -variate random (column) vector $\mathbf{x}$ with mean vector $\mu = (\mu_1, \dots, \mu_p)'$ and positive semidefinite covariance matrix $\Sigma = (\sigma_{ij})$. From standard matrix theory,^[16] there exists a $p \times p$ orthogonal matrix $\mathbf{W} = (\mathbf{w}_1, \dots, \mathbf{w}_p)$ such that

$$\mathbf{W}'\Sigma\mathbf{W} = \text{diag}(\lambda_1, \dots, \lambda_p) \quad (1)$$

where

$$\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_p \geq 0 \quad (2)$$

are the p eigenvalues of Σ in descending order. The k th column $\mathbf{w}_k$ of $\mathbf{W}$ is an eigenvector of Σ corresponding to the k th eigenvalue λ_k . Using the orthogonal matrix $\mathbf{W}$, we can then transform $\mathbf{x}$ into a new random vector $\mathbf{z} = (z_1, \dots, z_p)'$:

$$\mathbf{z} = \mathbf{W}'\mathbf{x} \quad (3)$$

The p variables z_k , ($k=1, \dots, p$), each being a linear combination of the p original variables x_k , are called the principal components of $\mathbf{x}$. Note that $\text{Cov}(\mathbf{z}) = \mathbf{W}'\text{Cov}(\mathbf{x})\mathbf{W}$, yielding $\text{Var}(z_k) = \lambda_k$. Thus, unlike the original variables x_k , which are correlated and may or may not have any order, the principal components are uncorrelated and ordered according to their variances: The first principal component z_1 has the largest variance, λ_1 , among all unit length linear combinations of $\mathbf{x}$, and the second principal

component z_2 has the largest variance, λ_2 , among all unit length linear combinations of $\mathbf{x}$ that are uncorrelated with z_1 , and so on, so that the k th principal component z_k has the largest variance, λ_k , among all unit length linear combinations of $\mathbf{x}$ that are uncorrelated with its $k-1$ preceding principal components. Another key property of principal components, as clearly seen from the construction process, is that the total variation in $\mathbf{x}$ as measured by

$$\text{tr}[\text{Cov}(\mathbf{x})] = \sum_{k=1}^p \text{Var}(x_k) = \sum_{k=1}^p \lambda_k \quad (4)$$

remains unchanged after transformation, i.e., $\text{tr}[\text{Cov}(\mathbf{z})] = \text{tr}[\text{Cov}(\mathbf{x})]$.

SAMPLE PRINCIPAL COMPONENTS

Often the principal components in Eq. 3 are called population principal components to reflect the dependence on the eigenvectors of the population covariance matrix Σ , which is in general unknown. In contrast, principal components derived based on the sample covariance $\mathbf{S}$, an estimator of Σ , are called sample principal components.

Let $\mathbf{x}_1, \dots, \mathbf{x}_n$ be n random observations of the p -variate random vector $\mathbf{x}$. The sample covariance matrix $\mathbf{S}$ is then given by

$$\mathbf{S} = \frac{1}{n-1} \sum_{i=1}^n (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})' \quad (5)$$

where $\bar{\mathbf{x}} = \sum_{i=1}^n \mathbf{x}_i / n$ is the sample mean vector. Now suppose $\hat{\lambda}_1 \geq \hat{\lambda}_2 \geq \dots \geq \hat{\lambda}_p \geq 0$ are the p eigenvalues, and $\omega_1, \dots, \omega_p$ the corresponding eigenvectors, of the sample covariance $\mathbf{S}$. Then the k th sample principal component is given by

$$t_k = \omega_k' \mathbf{x}, \quad k = 1, \dots, p \quad (6)$$

Replacing $\mathbf{x}$ by $\mathbf{x}_i$ in Eq. 6 yields the k th principal component score of the i th observation. These component scores, especially the first few leading ones, play an essential role in principal component analysis; statistical analysis procedures are executed with leading principal component scores instead of the original observations.

RELATED INFERENCE ON PRINCIPAL COMPONENTS

Principal component analysis involves estimation of the eigenvalues λ_k and eigenvectors $\mathbf{w}_k$ of the covariance matrix Σ . Suppose that the random vector $\mathbf{x}$ follows a multivariate normal distribution $N(\mu, \Sigma)$. The maximum likelihood estimates of λ_k and $\mathbf{w}_k$ can be obtained accordingly from the sample covariance matrix $\mathbf{S}$, the maximum likelihood

estimate of Σ . (If some eigenvalues are identical, then certain averaging is needed; see Ref. [17].)

Exact joint distribution of the sample eigenvalues (of $\mathbf{S}$), although of little practical use, is derived in Ref. [18]. Asymptotic distributions of the sample eigenvalues are developed by, among others, James^[18] and Anderson.^[19] Chapter 9 of Ref. [4] has a nice inclusion of these developments.

These distributional theories allow us to test some important hypotheses regarding principal components. For example, one can test whether the first several leading principal components selected in the analysis actually account for the desired level of total variance (see Eq. 7). Another important example is to test whether some of the smallest eigenvalues are equal. For these and other testing problems, readers are referred to Chapter 9 of Ref. [4] and Chapter 3 of Ref. [8].

COMPUTATION OF PRINCIPAL COMPONENTS

Many standard statistical packages have the capacity to perform principal component analysis. In both S-PLUS and SAS, the built-in function or procedure share a common name, “princomp.” These two software packages are able to handle most aspects of principal component analysis. Another software, SPSS, also has similar features but allows more rotation and graphical presentation of the principal components via a pull-down menu.

Several methods for numerical calculation of principal components are summarized in Ref. [8] including Hotelling's^[2] power method to compute the largest eigenvalue and its corresponding eigenvectors of a matrix, the QL algorithm and singular value decomposition method to compute all principal components and the corresponding eigenvectors. See Ref. [8] and the references therein for more information.

An important issue that complicates computation of principal components arises when the number p of variables is large. In a typical microarray experiment or medical imaging analysis, for example, p , the number of genes or pixels, is often at least in several hundreds. To compute the eigenvalues and eigenvectors of the $p \times p$ sample covariance matrix $\mathbf{S}$ hence becomes a daunting task and sometimes “mission impossible.” In addition to the methods cited above, a new procedure, block principal component analysis, is developed in Ref. [13] to deal with high dimensionality. The method first groups the p variables into a number of blocks so that variables in the same block have higher correlation than in two different blocks. Principal components of variables in each block are derived and then combined to yield principal components of the original variables. This approach not only simplifies the computation when p (and possibly n) is large, but also has the advantage to get insight into how and what variables are related.

SELECTING PRINCIPAL COMPONENTS FOR ANALYSIS

When replacing the p original variables by the first q ($q < p$) leading principal components in executing a statistical analysis procedure, an important issue is to determine the number q . The most popular (and straightforward) approach is to first specify a cut point $0 < \alpha < 1$ and then choose q such that the first q components explain at least 100α percent of the total variance among the original variables, i.e.,

$$\frac{\sum_{k=1}^q \lambda_k}{\sum_{k=1}^p \lambda_k} \geq \alpha \quad (7)$$

If the eigenvalues λ_k are unknown, then their sample estimates $\hat{\lambda}_k$ are used in Eq. 7.

In general, some loss of information will occur unless $\alpha = 1$. For a reasonably large α (> 0.8), the loss of information is often minimal, and in some cases may lead to more efficient estimation of parameters. (See the section on “Principal Component Regression.”)

A more sophisticated and statistically guided cross-validation procedure in choosing the number q is developed by Krzanowski.^[20] For each q , a predicted value $\hat{x}_{ik}$ of the i th observation of the k th variable x_{ik} is obtained based on the first q principal components obtained using the subset of data that does not include x_{ik} , and the prediction sum of squares is computed. The number q to be chosen is the one that has no significant decrease in the prediction sum of squares when additional principal components are added to the prediction model.

DATA VISUALIZATION

Data visualization via use of principal components is an important application in exploratory multivariate data analysis. With reduced dimensionality by principal component analysis, it is possible to visualize the observations in a two- or three-dimensional space to detect interesting patterns among the observations. To do so, for each observation, we compute, using Eq. 6, the first two or three principal component scores, and then plot these scores in a two- or three-dimensional space. Such visualization process provides not only insight into relationship among observations, but useful preliminary information as well for more sophisticated clustering analysis of the observations.

It should be pointed out that since graphical presentation of the data uses only the first two or three principal components, the visualization results may not reveal the true data structure, unless these components account for a reasonably large amount of information contained in the data.

As an example, we examine the microarray gene expression data of five antiestrogen-responsive and

Fig. 1 Three-dimensional visualization of gene microarray data. Δ, responsive variants; ○, resistant variants (From Ref. [21])

four -resistant variants of a human breast cancer cell line. Expressions of a total of 597 genes are measured and the objective is to investigate whether these genes provide discrimination information between responsive and resistant variants. Before building a discriminant model, we can utilize principal components to get some insight into the gene expression data. Fig. 1 plots the first three principal component scores of these variants in a three-dimensional space, and shows clearly that responsive variants are mostly fairly close to each other and so are the resistant variants. Examination of the variance shows that the first three principal components account for 81.2% of the total variance, implying that patterns shown in the figure are a fairly reliable reflection of the true data structure.

PRINCIPAL COMPONENT REGRESSION

Another important application of principal components is their role as independent variables in linear regression analysis. When large numbers of regressor variables are present in regression analysis, multicollinearities—linear functional relationship among some regression variables—may occur. Multicollinearities result in unstable estimates of regression parameters, often with large variances. One approach^[22–24] to overcome multicollinearity in regression is to replace the regressor variables by their first several leading principal components and then obtain the least squares estimation for the regression parameters. This approach will in general yield biased estimators of the regression parameters. However, with properly chosen principal components as the new regressor variables, the resulting estimators often possess smaller mean squared error.

To be specific, consider the linear regression model

$$\mathbf{y} = \beta_0 \mathbf{1}_n + \mathbf{X}'\boldsymbol{\beta} + \boldsymbol{\epsilon} \quad (8)$$

where $\mathbf{y}$ is the (column) vector of n observations of the dependent variable, $\mathbf{1}_n$ is the (column) vector of n 1s, and $\mathbf{X}$ is the design matrix of order $p \times n$, with the i th column often representing the i th vector of observations of the p regressor variables, the vector $\boldsymbol{\epsilon}$ consists of n i.i.d. random error terms with mean 0 and common variance σ^2 , and $\boldsymbol{\beta}$ is the vector of regression parameters. Without loss of generality, we can assume that the p rows of $\mathbf{X}$ are centered at 0, i.e., $\mathbf{X}\mathbf{1}_n = \mathbf{0}$, so that the matrix $\mathbf{X}\mathbf{X}'/n$ estimates the covariance matrix of the p regressor variables. With these assumptions, the least squares estimate $\hat{\boldsymbol{\beta}}$ of $\boldsymbol{\beta}$ is given by

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}\mathbf{X}')^{-1} \mathbf{X}\mathbf{y} \quad (9)$$

The mean squared error of $\hat{\boldsymbol{\beta}}$ is

$$\text{MSE}(\hat{\boldsymbol{\beta}}) = \sigma^2 \sum_{k=1}^p \lambda_k^{-1} \quad (10)$$

where $\lambda_1 \geq \dots \geq \lambda_p > 0$ are the p eigenvalues of the matrix $\mathbf{X}\mathbf{X}'$. Clearly, when multicollinearities occur, i.e., some of the λ s are close to 0, $\hat{\boldsymbol{\beta}}$ will have large variance, resulting in unstable estimation.

Now suppose that $\lambda_{q+1}, \dots, \lambda_p$ are the eigenvalues that are close to 0, causing multicollinearities. Let $\mathbf{W}$ be the matrix of order $p \times p$ whose k th column $\mathbf{w}_k$ is the eigenvector of $\mathbf{X}\mathbf{X}'$ corresponding to λ_k . Then the i th column of $\mathbf{Z} = \mathbf{W}'\mathbf{X}$ are the p principal component scores of the i th observation, $(x_{i1}, \dots, x_{ip})'$, on regressor variables. Put $\mathbf{W} = (\mathbf{W}_1, \mathbf{W}_2)$ with $\mathbf{W}_1 = (\mathbf{w}_1, \dots, \mathbf{w}_q)$ and $\mathbf{W}_2 = (\mathbf{w}_{q+1}, \dots, \mathbf{w}_p)$, and accordingly $\mathbf{Z} = (\mathbf{Z}_1', \mathbf{Z}_2')'$ with $\mathbf{Z}_1 = \mathbf{W}_1'\mathbf{X}$, and $\mathbf{Z}_2 = \mathbf{W}_2'\mathbf{X}$, corresponding to the first q and the remaining $p-q$ principal scores. Note that $\mathbf{X} = \mathbf{W}\mathbf{Z}$. The least squares estimate $\hat{\boldsymbol{\beta}}$ can be reexpressed as

$$\hat{\boldsymbol{\beta}} = (\mathbf{W}_1, \mathbf{W}_2) \text{diag}(\lambda_1^{-1}, \dots, \lambda_p^{-1}) (\mathbf{Z}_1', \mathbf{Z}_2')' \mathbf{y} \quad (11)$$

Retaining only the terms corresponding to the first q principal components leads to the principal component regression estimate of $\boldsymbol{\beta}$:

$$\tilde{\boldsymbol{\beta}} = \mathbf{W}_1 \text{diag}(\lambda_1^{-1}, \dots, \lambda_q^{-1}) \mathbf{Z}_1' \mathbf{y} \quad (12)$$

Applications of principal components in regression are not limited to linear models. For example, Barker and Brown^[25] investigated the application of principal components in logistic regression.

PRINCIPAL COMPONENTS BASED ON CORRELATION MATRIX

We have derived principal components based on the covariance matrix $\Sigma = (\sigma_{ij})$ or its estimator $\mathbf{S} = (s_{ij})$. When

some of the variables have relatively large variance as compared to others, often due to the use of different units of measurements of the variables, these variables may dominate the leading principal components, which is viewed as undesirable in many applications. An alternative approach is to use principal components of the standardized variables, obtained based on correlation matrix Ω with the (i, j) th elements $\omega_{ij} = \sigma_{ij}/(\sigma_{ii}\sigma_{jj})$, or its estimate $\hat{\Omega}$ with $\hat{\omega}_{ij} = s_{ij}/(s_{ii}s_{jj})$. Unlike principal components based on covariance matrix, the principal components derived this way are robust against large variances. It should be pointed out, however, that principal components derived from correlation matrix have no straightforward relation to those obtained from covariance matrix.

Recently, Boik^[26] developed distributional theory on correlation-based principal components. These theoretical developments allow us to test hypotheses regarding the correlation-based principal components.

INTERPRETATION OF PRINCIPAL COMPONENTS: A BIOMARKER EXAMPLE

In real studies, the original variables $\mathbf{x}$ are well designed and each has a clear practical meaning. However, the principal components, each being a linear combination of $\mathbf{x}$, may not be so, and interpretation of these components may be difficult and has to be carefully investigated. Here we present an example of biomarkers whose principal components turn out to be meaningfully interpreted.

Advanced laboratory procedures have provided a large collection of biomarkers of oxidative stress and antioxidant status. Individually, these markers contribute a broad spectrum of information on the oxidative stress status of an individual. However, because of their extensive number, limited knowledge is available on how to examine these biomarkers in combination, their relative significance on the oxidation/antioxidants process, and their interrelation. Considering measurements of prooxidant/antioxidant markers made in the same individuals, and by similar techniques, the likelihood of multicollinearity and multiple comparisons is of real concern when trying to clarify this intriguing process. These concerns need to be addressed when evaluating such biomarkers.

We utilize principal component analysis with 10 biomarkers measured in 925 men and women from a random sample of participants from Buffalo, New York, to obtain biologically meaningful linear combinations of these biomarkers related to oxidative stress and antioxidant status. We examine the first three principal components (based on sample covariance matrix), which explain 75% of the total variance of the 10 biomarkers. The three components are presented in Table 1, with coefficients that are 0 or close to 0 left blank.

Careful investigation reveals that these three components represent different aspects of the oxidative stress process.

Table 1 Principal Components of Oxidative Stress and Antioxidant Status Biomarkers

	Carotenoids	Oxidation	Antioxidants
β -Cryptoxanthin	.902		
β -Carotene	.676		
Lutein/Zeaxanthin	.649		
Lycopene	.462		
TBARS		.798	
Oxidized LDL		.701	-.206
Glucose		.666	
Triglycerides		.572	.309
Uric acid			.639
TEAC			.609

The first component consists of different types of vitamin A or carotenoids, including β -carotene, β -cryptoxanthin, lutein/zeaxanthin, and lycopene, giving the interpretation and name “carotenoids” to the component. The second factor reflects the effect of biomarkers related to oxidative stress, such as TBARS, oxidized LDL, glucose, vitamin E (part of the LDL molecule) and triglycerides, hence named “oxidation.” The third component, named “antioxidants” is characterized by antioxidant markers such as TEAC, uric acid, and triglycerides and negatively correlated with oxidized LDL.

In this application, 10 biomarkers are reduced to three leading principal components that retain most of the information. Each component has a sound scientific interpretation that requires deep understanding of subject matter.

CONCLUSION

Principal component analysis, as an exploratory multivariate data analysis technique, has been used in many other data analyses such as discriminant analysis, cluster analysis, and canonical correlation analysis, in addition to those described in the article.

Principal components are obtained through a series of variance maximization of the linear functions of the original variables. These optimal linear functions are, not surprisingly, different from the well-known Fisher's^[27] linear discriminant function because the objective functions are different; the latter is to minimize misclassification errors.

In principal component analysis, the first several leading principal components, which account for most of the variance, often play a far more important role than the others. There have been studies, however, that used the last few principal components to detect outliers and influential observations. (See Chapter 10 of Ref. [8] and the references therein.) When the first several principal components are used for analysis, it should be emphasized again that an

adequate number of components has to be selected to produce statistically reliable analysis results. If two or three components are used for data visualization (or pattern recognition), the information accounted for by these few components has to be evaluated.

Process Validation

James S. Bergum

Bristol-Myers Squibb Company, New Brunswick, New Jersey, U.S.A.

Merlin L. Utter

Pfizer Inc., Pearl River, New York, U.S.A.

Abstract

This entry focuses on the statistical techniques that aid in the validation of solid oral dosage forms, i.e., tablets and capsules. A general discussion of process validation is also provided.

INTRODUCTION

The Food and Drug Administration (FDA) defines validation in their 1987 publication *Guideline on General Principles of Process Validation*^[1] as “establishing documented evidence which provides a high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality characteristics.” Because this definition contains the phrases “high degree of assurance” and “consistently produce,” which have statistical implications, statisticians have been involved in developing acceptance limits and sampling plans as well as analyzing validation data for process validation programs.

Although process validation is applied to all product forms, this entry will focus on the statistical techniques that aid in the validation of solid oral dosage forms, i.e., tablets and capsules. A general discussion of process validation will also be provided. This entry should be of most interest to statisticians who want an overview of the concepts of process validation and a discussion of those statistical techniques that are most relevant. By including a number of examples, this article is written so that those who conduct validation studies can obtain appropriate acceptance criteria for practical use.

HISTORY AND OVERVIEW

Validation started in the early 1970s with assay verification. During the mid-1970s, most of the attention given to validation dealt with sterile processes because of the critical nature of injectable products. In the early 1980s, the FDA turned its attention to such nonsterile processes as solid dosage, semisolid dosage, liquids, suspensions, and aerosols. The draft process validation guideline was made available for comment in March 1983 and was issued in May 1987. The guideline was written to help industry comply with the 1978 revision of the “Current Good

Manufacturing Practices (cGMP) Regulations for Finished Pharmaceuticals” and the “Good Manufacturing Practice Regulations for Medical Devices.” This was the first time that the word validation had appeared in the regulations. Because following the cGMP is a legal requirement, failure to comply would constitute a violation of the Food, Drug, and Cosmetic Act.

Many authors have written about process validation.^[2–16] This introduction is a compilation from these papers. Process validation is performed on new drug products (both prescription and over-the-counter), active pharmaceutical ingredients, products involved in technology transfer (e.g., to a new manufacturing site), marketed products that have not been validated, and previously validated products that incurred a major change (e.g., in a processing step, a new raw material source for the active, manufacturing equipment, or process parameters).

Elements of the validation concept should be incorporated at each stage of the product and process development continuum. Identification of the critical process variables and studies aimed at establishing optimal ranges for these variables should be completed during the prevalidation phases. Statistics can play a major role in the prevalidation phases of assay validation, in the setting of specifications, and in formula screening/optimization studies. Some of the critical variables that need to be studied are: particle size of the drug substance, bulk density of the active drug/excipients, blender load, binder concentration, amount and spray rate of granulating fluid, blender speed and blending times, moisture content of the dried granulation, particle size of the lubricated granulation, and lubricant blending times. In fact, a number of major steps are involved in the development of stable, bioavailable, manufacturable, and cost-effective solid oral dosage forms. These include the physicochemical characterization of the drug substance, formulation development of commercial dosage forms, development and validation of analytical test methods, specification setting, scale-up and process optimization, development of stability data on commercial formulations packaged in the container/closure

systems to be marketed, and process validation. During the validation phase, sampling plans as well as acceptance criteria are needed. After the data are collected, a statistical review may be needed to evaluate the data against the preset acceptance criteria.

TYPES OF VALIDATION

There are three different types of process validation: retrospective, concurrent, and prospective. Retrospective validation covers those situations where a product is already marketed without a documented process validation program. Retrospective validation was not intended to be a method of validating new processes but rather a safety net that could be used to validate products already on the market at the time the validation requirements were put into the regulations. Retrospective validation has been used when there have been no changes in formulation, procedure, or equipment, and when the efficiency of the process can be judged from in-process and finished-product results. In retrospective validation, it is not sufficient to examine only pass/fail records on previously manufactured lots; a statistical analysis of quantitative data of product attributes is necessary to predict process capability. Retrospective process validation involves using historical data to provide documented evidence that a system does what it purports to do. Because most companies have completed their application of retrospective validation to existing products, it will not be discussed in this entry. However, a discussion of some analysis techniques that might be used when performing a retrospective validation can be found in Kohberger.^[17]

Prospective process validation involves proving that the process does what it purports to do based on a preplanned protocol and before the process is put to commercial use. It involves the collection and evaluation of data on at least three consecutive successfully manufactured batches matching routine production in all aspects of production and control. The statistical aspects of prospective validation will be discussed in this entry. The protocol should state the process steps, identify the controls to be used, specify the variables to be monitored, state what samples are to be taken both for testing and as contingency, specify both the product performance characteristics/attributes to be evaluated and their acceptance criteria, and refer to the test methods to be used. Historical data from formulation development and scale-up studies may help to set these criteria.

Concurrent validation is similar to prospective validation except that batches are validated and released one batch at a time. Concurrent validation is only accepted in limited situations, e.g., for orphan drugs where it is deemed an economic hardship to produce three batches at one time when all cannot be sold. The validation procedures and acceptance criteria are similar to what would be carried out for a prospective validation.

SAMPLING

A manufacturing process may involve drying and granulation steps as well as intermediate and final mixing steps. Once a blend has been mixed, it may be transported to another location for screening or tableting (or encapsulation). Sampling can be performed at any of these steps in the manufacturing process. Samples can be taken when the blend is in a mixer, while being discharged from the mixer, when it is in a transport container (e.g., drum), throughout tablet compression or encapsulation, and after film coating (if appropriate). Sampling plans need to be developed at each of these stages.

There are two sampling plans that are generally used when testing blends or final product. In the first plan (Sampling Plan 1), a single test result is obtained from each location sampled. For example, in a blending step, a single test result would be obtained from each of a number of different locations within the blender. In a drum, a single test result might be obtained from the different locations within the drum or from each of a number of different drums. For final tablets, a single tablet may be tested from various time points throughout the tableting run. In the second plan (Sampling Plan 2), more than one test result is obtained from each of the sampled locations. For example, during the tableting operation, if a cup is placed under the tablet press at specific time points during the tableting run, several of the tablets from each cup sample would be tested for content uniformity. Sampling Plan 2 allows for estimation of between-location and within-location variability.

It is assumed for the remainder of this entry that the same number of units is tested from each of the sampled locations; that is, it is a balanced sampling plan. Regardless of what sampling plan is used to determine testing, multiple units are normally collected at each of the sample locations during validation to serve as contingency samples for possible later testing.

Powder Blend Sampling

Based on the interpretation of the Wolin court decision (*United States vs. Barr Laboratories*), the allowable size of sample taken from powder blends has been set at no more than three times the dosage unit weight. A perplexing problem facing manufacturers of oral solid dosage forms today is the difficulty in applying this unit dose sampling to blend uniformity validation because of the current limitations in sampling technologies. An excellent discussion of blend sampling is given in the PDA Technical Report on Blend Uniformity.^[18] Much of the following discussion is taken from that paper.

There is a great deal of frustration among oral solid dosage form manufacturers caused by unit dose sampling of blends. Companies have obtained very uniform results when testing the finished dosage form (i.e., tablets or capsules) while obtaining highly variable results when

attempting to comply with the current FDA position on blend uniformity sampling.

It is generally recognized that a thief is far from an ideal sampling device because of a propensity to provide non-representative samples, i.e., the sample has significantly different physical and chemical properties from the powder blend from which it was withdrawn. Although simple in concept, demonstrating blend uniformity is complicated by this potential for sampling error. The current technology does not yet provide a method for consistently obtaining small representative samples from large static powder beds. Using X-ray fluorescence and near-infrared spectroscopy methods to measure blend uniformity, it is hoped that these problems may soon be overcome.

As stated in the PDA Technical Report,^[18] sampling error can be influenced by: (i) the design of the thief; (ii) the sampling technique; and/or (iii) the physical and chemical properties of the formulation. The physical design of the thief can affect sampling error because the overall geometry of the thief can influence the sample that is collected. Surface material can fall down the side slit of a longitudinal thief as it is inserted into a powder bed. Sampling technique can also have an impact on sampling error. As the thief is inserted into a static powder, it will distort the bed by carrying material from the upper layers of the mixture downward toward the lower layers. The angle at which the thief is inserted into the powder bed can also influence sampling error. Another factor that can affect sampling error is the physical and chemical properties of the formulation. The force necessary to insert a long thief into a deep powder bed can be appreciable. This force, depending on the physical properties of the formulation, can lead to compaction, particle attrition, and further distortion of the bed. Ideally, the thief should be constructed from materials that do not preferentially attract the individual components of the formulation. In general, the potential for sampling error increases as the size of the sample and/or the concentration of drug in the formulation decreases. Samples obtained using thief probes can be subject to significant errors.

Finished Product Sampling

Two of the most common tests for finished product that have acceptance criteria are content uniformity and dissolution. The United States Pharmacopeia (USP 32) requirements for content uniformity for solid oral dosage forms (e.g., tablets and capsules) as well as for dissolution are summarized in [Tables 1,2](#).

When collecting samples to evaluate these tests, it is important to maintain the location identity of all samples taken and to maintain this identity throughout the testing regimen. Validation is the one time when the exact location in the batch is known for each of the individual dosage units tested. By showing that each of the sample locations tested provides acceptable results, a justification is developed for

Table 1 USP 32 Content Uniformity Test Requirements

Stage	Number tested	Pass stage if:
S ₁	10	$ M - \bar{X} + 2.4s \leq 15.0$, where M is defined below, $\bar{X}$ is the sample mean, and s is the sample standard deviation
S ₂	20	i. $ M - \bar{X} + 2.0s \leq 15.0$ using all 30 results (S ₁ + S ₂) ii. No dosage unit is outside the maximum allowed range of 0.75M to 1.25M.

M is defined as follows:

If T is less than or equal to 101.5%, and

- If $\bar{X}$ is less than 98.5%, then $M = 98.5\%$.
- If $\bar{X}$ is between 98.5 and 101.5%, then $M = \bar{X}$.
- If $\bar{X}$ is greater than 101.5%, then $M = 101.5\%$.

If T is greater than 101.5%, and

- If $\bar{X}$ is less than 98.5%, then $M = 98.5\%$.
- If $\bar{X}$ is between 98.5 and T, then $M = \bar{X}$.
- If $\bar{X}$ is greater than T, then $M = T$.

Where T is the Target content per dosage unit at the time of manufacture, expressed as a percentage of the label claim. Unless otherwise specified in the individual monograph, T is 100.0%.

All measurements of dosage units and criteria values are in percentage label claim.

Table 2 USP 32 Dissolution Test Requirements

Stage	Number tested	Pass stage if:
S ₁	6	Each unit is not less than $Q + 5\%$
S ₂	6	Average of 12 units (S ₁ + S ₂) is equal to or greater than Q and no unit is less than $Q - 15\%$
S ₃	12	Average of 24 units (S ₁ + S ₂ + S ₃) is equal to or greater than Q , not more than 2 units are less than $Q - 15\%$, and no unit is less than $Q - 25\%$

the later combining of tablets or capsules into a QC composite sample for the release testing of future batches. If a two-sided press is used for tableting, the identity of the side of the press from which the samples were taken should also be maintained.

It is recommended that individual dosage units be tested from as many different sample locations as possible. The number of units tested could even be tied to run length, with more units tested when the run length goes across multiple shifts. A discussion of the effect of sample size on one of the methods discussed, the Bergum approach, is provided in the "Effect of Sample Size" section. Because Sampling Plan 2 allows for the estimation of both between and within-location variability, this plan is generally recommended when testing individual dosage units for content uniformity. For dissolution, one might choose either Sampling Plan 1 or Sampling Plan 2, depending upon how many total units are tested.

STATISTICAL TECHNIQUES/APPROACHES

Since the start of validation in the late 1970s, there has been little published material on the statistical aspects of conducting a successful process validation. What follows are some of the statistical techniques that have been either suggested in the literature or used in practice when conducting validation studies. Their use in the development of validation criteria will be discussed in the “Comparison of Acceptance Criteria” section. The Bergum approach is discussed in two papers by Bergum.^[19,20] A discussion of the other techniques can be found in Hahn and Meeker.^[21] Other techniques that have been applied to validation data but are not discussed in detail in this article are analysis of variance (ANOVA) and process capability analysis. In the following subsections, let $\bar{X}$ and s denote the mean and standard deviation of a sample of size n and let t and F be the critical values for the t and F distributions with their associated degrees of freedom and confidence levels. Let MSB be the between-location mean square from the one-way ANOVA.

Tolerance Interval

A tolerance interval is an interval that contains at least a specified proportion P of the population with a specified degree of confidence, $100(1 - \alpha)\%$. This allows a manufacturer to specify that at a certain confidence level at least a fraction of size P of the total items manufactured will lie within a given interval. The form of the equation is: $\bar{X} \pm ks$ where k = the tabled tolerance factor and is a function of $1 - \alpha$, P , n and whether it is a one-sided or two-sided interval.

Prediction Interval

A number of prediction intervals can also be generated. A “two-sided prediction interval for a single future observation” may be of interest. This is an interval that will contain a future observation from a population with a specified degree of confidence, $100(1 - \alpha)\%$. The form of this equation is: $\bar{X} \pm ks$ where $k = t_{1-\alpha/2, n-1} \sqrt{1 + 1/n}$.

Another type of prediction interval that might be of interest is a one-sided upper prediction interval to contain the standard deviation of a future sample of m observations, again with a specified degree of confidence, $100(1 - \alpha)\%$. This is called the standard deviation prediction interval (SDPI). The form of this equation is: $s\sqrt{F_{1-\alpha, m-1, n-1}}$.

Confidence Interval

Confidence intervals can be generated for any population parameter. Specifically, a two-sided confidence interval about the mean is an interval that contains the true unknown mean with a specified degree of confidence,

$100(1 - \alpha)\%$. The form of this equation, which depends on the sampling plan, is as follows:

- Sampling Plan 1 $\bar{X} \pm ks$ where $k = t_{1-\alpha/2, n-1} / \sqrt{n}$
- Sampling Plan 2 $\bar{X} \pm k\sqrt{\text{MSB}}$

$$\text{where } k = \frac{t_{1-\alpha/2, \# \text{ locations}-1}}{\sqrt{(\# \text{ locations})(\# \text{ per locations})}}$$

Note that for any stated confidence level, the confidence interval about the mean is the narrowest interval, the prediction interval for a single future observation is wider, and the tolerance interval (to contain 95% of the population) is the widest.

Variance Components

Variance components analysis has been used in a number of applications within the pharmaceutical industry. The power of this statistical tool is the separation or partitioning of variability into nested components. The approach requires using Sampling Plan 2 so that the between-location and within-location variance components can be estimated. These estimates can be calculated using one-way ANOVA. The within-location variance is estimated by the mean square error, whereas the between-location variance is estimated by subtracting the mean square error from the mean square between locations and then dividing by the number of observations within each location. When applied to the blending operation, the method allows us to determine the between-location variance, which quantifies the distribution of active throughout the blend, and the within-location variance, which in turn is composed of sampling error, assay variance, and a component related to the degree of mixing on the “micro” scale. The total variance in the container or mixer is the sum of the two variance components. Similarly, one may also determine these components in the product. Here the within-location variance will again consist of the assay variance, the sampling error, and the “micro” mixing component, in addition to the weight variation. The between-location component is that variance associated with macro changes in the blend environment. It is this component that reflects the overall uniformity of the blend and is minimized when optimum blender operation is achieved.

Simulation

Monte Carlo simulation can be used to estimate the probability of passing multiple-stage tests such as content uniformity and dissolution. This technique is performed by generating computer-simulated data from a specific probability distribution (e.g., normal) and then using these generated sample data as if they were actual observations. The multiple-stage test is then applied to the data. This process can be repeated many times to evaluate various

test properties (e.g., determining the probability of passing the multiple stage test for specific values of the population mean and standard deviation of a normal distribution).

Bergum Approach

Bergum^[19,20] published a method for constructing acceptance limits that directly relates the acceptance criteria to multiple stage tests such as the USP 32 content uniformity and dissolution tests. These acceptance limits are defined to provide, with a stated confidence level $(1 - \alpha)100$, a stated probability (P) of passing the test. For example, one can make the statement that, with 95% confidence, there is at least a 95% probability of passing the USP 32 test. Both the USP 32 content uniformity and the USP 32 dissolution tests have been evaluated. In each case, the required limits are provided in “acceptance tables,” which are computer generated. These tables change with the confidence level $(1 - \alpha)$, the probability bound or coverage (P), and the sample size (n) for content uniformity as well as the Q value for dissolution. Confidence levels as well as values for P are typically 50%, 90%, or 95%. The PDA Technical Report^[18] suggests the use of a 90% confidence level to provide 95% coverage. The FDA prefers a 95% confidence level. A 50% confidence level can be considered a “best estimate” of the coverage. A SAS program has been written to construct these acceptance limit tables for the USP 32 content uniformity and dissolution tests for both Sampling Plans 1 and 2. The computer program can be obtained by contacting James Bergum at Bristol-Myers Squibb.

Statistical Basis

The Bergum approach uses the fact that these are multiple-stage tests. A multiple-stage test is a test with several stages, where each stage has requirements for passing the test. As can be seen in Tables 1–2, the USP 32 content uniformity and dissolution tests are multiple-stage

tests with multiple criteria at each stage. The lower bound, LBOUND (also called P), for the probability of passing the USP 32 content uniformity and dissolution tests uses the following relationship:

$$\text{Prob}(\text{passing USP 32 test}) \geq \max\{\text{Prob}(\text{passing } i\text{th stage})\}$$

Where $i = 1$ to S (S = number of stages in USP 32 test).

One requirement for this inequality to hold for a multiple-stage test is that failure of the overall test at any stage also results in failure of the overall test at any subsequent stage.

Assume that the test results follow a normal distribution with mean μ and standard deviation σ . Sigma (σ) is the standard deviation of a single observation. For a given value of μ and a given value of σ , LBOUND can be determined by calculating the probability of passing all of the requirements at each stage. Figs. 1 and 2 show the 95% contours for the calculated bound LBOUND. If μ and σ are on the 95% LBOUND contour, then at least 95% of the samples tested using the USP 32 test would pass the test. Tables 3 and 4 compare these lower bounds to the “actual” probability of passing these tests for selected values of μ and σ . The “actual” probabilities were determined by simulating the USP tests. Note that these probabilities are for passing the overall test. The probability of passing stage 1 can be much smaller, especially for dissolution (e.g., there is less than a 1.6% chance to pass stage 1 dissolution if the population mean is $Q + 5$ with a sigma of 7).

The LBOUND can be used to develop acceptance criteria by constructing a simultaneous confidence interval for μ and σ from the data. If a 90% confidence interval were constructed for μ and σ and the entire interval were below the 95% LBOUND, then, with 90% confidence, at least 95% of the samples tested would pass the USP 32 test. For Sampling Plan 1, the sample mean and sample standard deviation estimate the population parameters μ and σ . A simultaneous confidence interval for μ and σ is given in Lindgren.²² Because the variance of a single observation

Fig. 1 Ninety-five percent contour plot for probability of passing USP 32 content uniformity test

Fig. 2 Ninety-five percent contour plot for probability of passing USP 32 dissolution test

using Sampling Plan 2 is the sum of the between-location and within-location variances, σ (i.e., the standard deviation of a single observation) is estimated by calculating the square root of the sum of the between-location and within-location variance components. A confidence interval for σ is given by Graybill and Wang.^[23] The simultaneous confidence interval for μ and σ is constructed by using a Bonferroni adjustment on the two individual confidence intervals for μ and σ . Once the confidence interval is constructed, it must fall completely below the LBOUND specified. An acceptance limit table can be generated by finding the largest sample standard deviation for a fixed sample mean such that the resulting confidence interval remains below the prespecified LBOUND.

Effect of Sample Size

Through the use of operating characteristic (OC) curves, the effect of sample size on the ability to pass the Bergum approach for content uniformity (CU) can be evaluated. The OC curves provide estimates of the probability of passing the Bergum approach over a number of different population mean and standard deviation values. Figs. 3 and 4 provide OC curves for specific sample sizes using Sampling Plans 1 and 2, respectively. For these plots, a mean of 100% was assumed. A confidence level of 90% to obtain 95% coverage was also used. The estimated probability of passing the USP 32 content uniformity test was included for comparison.

Fig. 3 provides the OC curves using Sampling Plan 1 for sample sizes of 10, 30, 60, 100 and 2000. As expected, the probability of passing the acceptance limit table increases as the sample size increases. For example, if n is 30, the probability of passing the acceptance limit table for tablets when σ is 4.0% is approximately 75%. To increase the probability of passing the Bergum approach with this type of true quality, a larger sample size would be needed. The probability of passing the USP test is also provided to show how much more discriminating the Bergum Tables can be.

Table 3 Simulated (SIM) vs Lower Bound (LB) Probabilities of Passing CU Test

Population mean μ	Method	Population standard deviation σ		
		2	4	6
88	LB	0.800	0.024	0.004
	SIM	0.852	0.028	0.004
92	LB	1.000	0.674	0.072
	SIM	1.000	0.739	0.096
96	LB	1.000	1.000	0.610
	SIM	1.000	1.000	0.695
100	LB	1.000	1.000	0.964
	SIM	1.000	1.000	0.972
104	LB	1.000	1.000	0.610
	SIM	1.000	1.000	0.692
108	LB	1.000	0.674	0.072
	SIM	1.000	0.743	0.095
112	LB	0.800	0.024	0.004
	SIM	0.858	0.028	0.003

Table 4 Simulated (SIM) vs Lower Bound (LB) Probabilities of Passing Dissolution Test

μ Expressed as distance above Q	Method	Population standard deviation Σ		
		3	5	7
1	LB	0.949	0.836	0.753
	SIM	0.966	0.889	0.823
3	LB	1.000	0.998	0.981
	SIM	1.000	0.999	0.988
5	LB	1.000	1.000	0.999
	SIM	1.000	1.000	0.999

For example, when the probability of passing the USP test gets down to 95% or below, the probability of passing the Bergum tables for these OC curves is essentially zero.

Fig. 4 provides the OC curves using Sampling Plan 2 for a sample size of 60 but with different numbers of locations sampled; the results are compared to the use of Sampling Plan 1 without any replication. It is assumed for this plot that half of the total variation is due to between-location variance and half is due to within-location variance (i.e., factor = 0.5). Note that the number of locations has a significant effect on the probability of passing the acceptance limit table. This effect would have been even larger if the percent of variation due to locations was assumed to have been something greater than one half. It is recommended that when using Sampling Plan 2, the number of locations used be as large as possible. For example, if a total of 60 tablets are sampled across the batch, it is better to sample 3 from each of 20 locations than to sample 20 from each of 3 locations.

Fig. 3 Probability of meeting Bergum CU acceptance table for Sampling Plan 1, $\mu = 100.0\%$, 90% assurance/95% coverage, tablets

Fig. 4 Probability of meeting Bergum CU acceptance table for Sampling Plan 2, $\mu = 100.0\%$, 90% assurance/95% coverage, factor = 0.5, tablets

COMPARISON OF ACCEPTANCE CRITERIA

There are a number of tests that are performed during validation. In the blends, the primary interest is in showing that the blend is uniform in drug content. Uniformity can also be evaluated in the drums to ensure that segregation or demixing did not occur during transfer. The overall potency is generally not considered a critical variable in the blends because it is neither enhanced nor diminished by additional mixing. However, there may be a concern with potency loss during processing or storage between

processing steps, e.g., after emptying the blended powder into transports or as a result of tablet compression. In the final product, content uniformity and dissolution are of primary interest, and to a lesser extent, potency. Acceptance limits are generally developed for these tests. Other tests that are performed, such as particle size, bulk/tap density and flow, hardness, friability, and weight variation, may or may not have formal, statistically derived acceptance limits.

There are almost as many approaches to validation as there are companies performing validation. What follows

Table 5 Advantages and Disadvantages of Various Statistical Techniques for Powder Blends

Test	Advantages	Disadvantages
<i>Blend uniformity</i>		
1. FDA approach	Accepted by the FDA	Not statistically based Penalized for large n Adversely affected by constant loss of potency
2. SDPI	Rewarded for larger n Not affected by constant loss of potency Can be tied to part of Stage 1 USP 32 CU test	Difficult to apply with Sampling Plan 2 Not directly tied to full USP 32 CU test
3. Tolerance interval	Easy to calculate Rewarded for larger n	Not directly tied to full USP 32 CU test Difficult to apply for Sampling Plan 2 Factors can be hard to find for nonstandard coverage probabilities
4. Bergum approach	Rewarded for larger n Tied directly to USP 32 overall test Easy table look-up Provides high assurance of passing USP 32 test	Computer program required (but can be provided) Difficult to pass using Sampling Plan 2 with few locations
5. Holistic approach	Provides chance to recover from variable blender results	Substitution of variance components concept may be a hard sell Degrees of freedom can be significantly reduced

Table 6 Advantages and Disadvantages of Various Statistical Techniques for Finished Product (Tablets/Capsules)

Test	Advantages	Disadvantages
<i>CU/dissolution</i>		
1. Simulation	Directly tied to USP 32 Can be tied to either Stage 1 or full test Can handle non-symmetric potency limits	Not a function of n Does not provide high assurance level of passing USP 32 test (only point estimate)
2. Tolerance interval	Easy to calculate Rewarded for larger n	Not tied directly to USP 32 overall test Difficult to apply for Sampling Plan 2 Factors can be hard to find for nonstandard coverage probabilities
3. Bergum approach	Rewarded for larger n Tied directly to USP 32 overall test Easy table look-up Provides high assurance of passing USP 32 test	Does not directly address non-symmetrical potency limits Computer program required (but can be provided) Difficult to pass using Sampling Plan 2 with few locations
<i>Potency (composite assay)</i>		
1. Confidence interval	Provides strong statement that overall batch average potency is acceptable	Does not provide assurance that a given assay result will meet requirements
2. Tolerance/prediction interval	Provides strong statement that an individual assay result will meet assay requirements	Requires a large number of composite assays

is a discussion of some of the methods of statistical analysis along with their advantages and disadvantages. Two proposals, one from the FDA for blends and another by the Parenteral Drug Association (PDA), called a “Holistic” approach to validation, are also discussed.

The advantages and disadvantages of these methods are listed in [Tables 5](#) and [6](#) for powder blends and finished product (tablets/capsules), respectively. Note that what might be an advantage to one person can be a disadvantage to the next.

Powder Blends

Blend Uniformity

The Food and Drug Administration Approach The FDA has proposed the following acceptance criteria for blend uniformity testing.^[24]

- Each individual sample should meet compendial assay limits (e.g., 90.0–110.0%).
- The RSD should be no greater than 5%.
- A minimum of 10 samples should be tested.

The samples should include potential “dead spots.” The tighter RSD requirement is to allow for additional variation from possible demixing and weight or fill variation. It is stated^[24] that just meeting the USP 32 content uniformity criteria is not appropriate for blends. The blend criteria also should not be relaxed because of sampling difficulties. It is more appropriate to change the sampling procedure to ensure accurate results.

The advantages of these criteria are that they are easily understood and implemented and any firm that meets them would be highly confident of satisfactorily passing a GMP or preapproval inspection. However, these criteria have a number of disadvantages. A firm is penalized for taking more samples because the probability of finding an out-of-range sample increases accordingly. These criteria also assume that current sampling practices can always provide a consistent collection of unit dose samples representative of the powder blend.

Standard Deviation Prediction Interval Because uniformity is of primary interest in powder blend validation and because of a concern that a constant sampling error can occur, one approach is to base the criteria on variability only. The SDPI allows one to predict, from a sample of size n , and with a specified level of assurance, an upper bound on the standard deviation of a future sample of size m from the same population. This approach is recommended in the PDA paper on blend uniformity.^[18]

By setting the future sample size m to 10, which is the stage 1 sample size for the USP 32 content uniformity test, and by requiring that the upper bound on the standard deviation of a future sample of size 10 be less than 6.25% (i.e., 15/2.4), which is the USP 32 stage 1 upper limit on the standard deviation if $M - \bar{X} = 0$, the SDPI approach can be tied to the USP 32 content uniformity test. The SDPI equation in the “Statistical Techniques/Approaches” section can be rearranged to obtain the following equation: $S_{cr} = S_m / [F_{1-\alpha, m-1, n-1}]^{1/2}$ where n = size of current sample; s_{cr} = critical standard deviation; s_m = upper bound of a future sample of size m ; $1 - \alpha$ = confidence level (e.g., 0.90); F = critical F value.

S_{cr} becomes the maximum acceptable sample standard deviation to meet the acceptance criteria. If the sample

standard deviation, s_n , is less than s_{cr} , then we are guaranteed, with a minimum assurance of $100(1 - \alpha)\%$, that the upper prediction bound for a future sample of size 10 will not be greater than 6.25% of the target concentration.

Tolerance Interval Approach To use the tolerance interval as an acceptance criterion, the confidence level $100(1 - \alpha)\%$ and coverage level P need to be chosen. One approach is to assume that the blend samples are the same as the resulting final product from that blend. To tie the tolerance interval to the USP 32 content uniformity test, one choice might be to use a coverage of 96.7% because the USP 32 test was developed based on matching the operating characteristic operating curves to the previous USP content uniformity test for tablets which allowed 1 tablet out of 30 (96.7%) to be outside 85–115% of label claim. If the tolerance interval is completely contained within the 85–115% interval, these acceptance criteria would be met. Another choice of how to define the coverage P is discussed in the PDA technical report.^[18] Although it is difficult to find tolerance factors for nonstandard coverage levels in published tables, they can be generated using the interval statement in the SAS/QC[®] procedure CAPABILITY.^[25]

Tolerance intervals assume that sampling is performed using Sampling Plan 1. There is only one variance component used to estimate the variance of a single observation, i.e., the sample variance. The degrees of freedom used to determine the tolerance factor k is the degrees of freedom associated with the sample variance. However, if Sampling Plan 2 is used, there are two variance components used to estimate the variance of a single observation. Therefore the degrees of freedom must be approximated. This can be carried out using Satterthwaite' approximation.^[26]

Bergum Approach Because the USP 32 content uniformity test is applied only to the finished product, the application of the Bergum approach requires that the acceptance limits for the blend be tied to the limits for the dosage form. In addition, for any of the approaches, each result is generally expressed in percentage of label claim as a percentage of active in a theoretical tablet weight. An alternative to the SDPI approach, which is not dependent upon the mean, is to express each result as a percentage of the sample mean and to then apply the Bergum approach. This has the effect of removing the mean effect and just evaluating the variability. If this were carried out, then the acceptance limit would be the RSD associated with a sample mean of 100%.

Holistic Approach The PDA report^[18] proposes a “Holistic” approach to the validation, in which means and variances of the blend are compared to the means and variances of the final product. The validation is considered successful if all criteria are met for both the blend and the final dosage form. If the final product fails, the validation is unsuccessful regardless of the blend results. However,

there are situations where the final product is acceptable and the blend is unsuccessful but the true blend uniformity can be deemed acceptable. This is because the inconsistent results might be due to sampling error when sampling the blend. The blend may have good location-to-location variability, but, because of sampling errors, the within-location error causes the blend results to fail. One approach given by the PDA paper^[18] is to use “analysis by synthesis.” To employ this technique, Sampling Plan 2 must be used for both the blend and the final dosage form so that the between-location and within-location variance components can be estimated. These variance components, as well as the total variance, can be statistically tested using an *F* test to determine if there is a significant difference between the variances at the two stages. If the within-location variance component in the blend is significantly higher than that in the final product, then the within-location variance component for the final product is substituted for the within-location variance component of the blend, in an attempt to remove the effect of sampling error in the blend sample results. This reduced overall variance for the blend is compared to the acceptance criteria.

Average Potency

There may be a desire to assess possible potency loss between the different sample stages. There also may be an interest in assessing whether the average potency results are at the target potency. At the blender stage, the average potency can be determined either from taking the average of several potency assays or by using the average of the uniformity values if it is felt that there are no sampling issues associated with the smaller sample quantity and if the assay and content uniformity methods are the same. If it is not clear whether there will be sampling issues during validation, it is suggested, when possible, that a formulation study be conducted prior to the validation to determine whether the smaller sample quantity will provide consistent uniformity results and, if not, what sample quantity will produce consistent results. With this support in hand, the smallest sample quantity that will provide consistent results should be used for the validation. It is understood, however, that it may not always be possible to conduct such prevalidation studies.

If a comparison across stages is to be performed, it is recommended that all powder results be reported as percentage of label claim, and not as a percentage of theoretical, so as to provide a direct comparison of the average results to finished product. One must remember that the potency results obtained prior to any addition of lubricant must be adjusted down to account for the noninclusion of the lubricant at the time of sampling. To compare the average uniformity or potency results across stages, one can require that the averages at each stage be within some stated amount of each other or of target. Statistically based techniques such as ANOVA or confidence intervals using the variation of the data and a stated assurance level can also be used.

Finished Product

Content Uniformity/Dissolution

Bergum Approach This approach is recommended in the PDA paper^[18] for final product testing. To use the dissolution acceptance limit tables, the value of *Q* is required.

Simulation One approach is to assume that the sample mean and the standard deviation are the true population mean and standard deviation, to provide a “best estimate” of the true probability of passing. This has the advantage that it can provide estimates of the probability of passing at any stage and can handle the nonsymmetrical potency shelf life limits in the content uniformity test. The disadvantage is that it does not provide a bound on the probability with high assurance and is not a function of sample size. However, it can provide a good summary statistic of the content uniformity data.

Tolerance Interval See the “Tolerance Interval Approach” section for comments regarding the use of tolerance intervals as acceptance limits for content uniformity data. Tolerance intervals can also be used as acceptance limits for dissolution. Because the USP 32 dissolution test for stage 1 is that all six capsules be greater than $Q + 5$, the tolerance interval could be tied to the USP 32 test by requiring that the lower bound on the tolerance interval be greater than $Q + 5$. To obtain a 95% probability of passing at stage 1, the coverage *P* of the tolerance interval would need to be $(0.95)^{1/6}$, or 0.991. Using a tolerance interval based on stage 1 of the USP 32 test can be very restrictive.

Confidence Interval Confidence intervals are not recommended for evaluating content uniformity data. However, an approach that is less restrictive than tolerance intervals for evaluating dissolution data is to base the acceptance limits on meeting the second and third stage of the USP 32 dissolution test. Both the second and third stages require that the sample mean be less than *Q*. Therefore a lower one-sided confidence interval for the population mean could be used as an acceptance limit. The criterion is that the lower bound on the confidence interval must be greater than *Q*.

Potency

Potency can also be evaluated during validation. It is assumed that some number of composite assays is tested during validation. One criterion might be to generate a $100(1 - \alpha)\%$ confidence interval about the mean using all the potencies collected. This interval will contain the true batch potency with $100(1 - \alpha)\%$ confidence. This interval should be contained within the potency “in-house” or release limits. Enough potency results should be looked at to have sufficient power that this interval will be contained within the desired limits.

Meeting the foregoing criterion should not be interpreted to mean that an individual composite potency assay will meet the “in-house” limits with high assurance. If this is desired, a prediction interval for a single future observation or, better yet, a tolerance interval should be used. The validation specialist should be cautioned that additional composite assays might need to be tested to meet either one of these criteria with high confidence.

At a minimum, each of the composite assay results obtained should fall within the desired limits, either the potency shelf specifications or the potency “in-house” (or release) limits. The “in-house” limits are felt to be the more appropriate because these are the limits that ensure that the product will meet the shelf limits throughout expiry.

Other Validation Issues

Validation data should be plotted whenever possible. For example, content uniformity and dissolution can be plotted versus the sample locations. This allows for a visual check for trends. A criterion requiring “no trends of note” or that some specific trend rule be met (such as Nelson’s mean square successive difference trend test^[27]) might be included as part of the acceptance criteria. Some companies use more of a process-capability approach to determine consistency of test results across sample locations.

It is desirable that samples be sent to the laboratory for testing in a designed and ordered way, to be able to separate laboratory effects from process effects if it becomes necessary. For example, if four units were to be tested from each sample location, send one half of the units from each location to the laboratory on each of 2 days. In practice, the laboratory may resist doing this.

Weights of individual dosage units should be obtained for every unit tested for both content uniformity and dissolution at the time the units are tested. This may be useful information for later investigation if unacceptable test results are obtained.

For coated products, because this is the finished form, sampling and testing should also be conducted. However, the emphasis is usually on the cores, where the sample identity across the batch is known and can be evaluated. At the coated stage, the effect of the coating solution on dissolution is probably of most interest. Individual coating pans, either all of them or some portion of them, should be sampled and tested, with pan number identity maintained.

FUTURE DIRECTIONS

Recently, a new draft guidance for industry on process validation has been issued for comments.^[28] Though not yet approved, it reinforces the importance of statistics in the process validation process. This draft guidance incorporates the FDA’s initiative on “Pharmaceutical cGMPs for the 21 st century” and is aligned with ICH

guidance documents such as Q8, Q9, and Q10. It is based on the principle that process validation should take place over the lifecycle of the product and process, not just the first three batches produced, and it emphasizes the importance of building process knowledge and understanding, establishing a strategy for process control, and maintaining a state of control throughout the lifecycle. The basis of process understanding and process evaluation is the use of sound statistical methods and procedures such as are provided in this chapter.

EXAMPLES

The two examples given in this section demonstrate the application of some of the statistical techniques described in previous sections using both Sampling Plans 1 and 2. Example 1 uses Sampling Plan 1 and Example 2 uses Sampling Plan 2. In each example, samples are taken from the blend and from the final product. Samples from both the blend and final capsules are tested for content uniformity. The final capsules are also tested for dissolution. We assume that the USP 32 dissolution specification for this immediate release product has a Q of 85% at 30 minute. Suppose the blend samples are taken from a V blender. This type of blender looks like a V with a left and right side of the V. Samples are taken from the front and back of each side of the blender from the top, middle, and bottom of the granulation, for a total of 12 locations. Assume that the data are in percentage of label claim units. Although a 90% confidence level is used throughout the example, 95% is also a typical confidence level. For the Bergum approach, a 95% probability of passing is used throughout. All tolerance factors were calculated using the interval statement in the SAS/QC procedure CAPABILITY.^[25]

Example 1 (Sampling Plan 1)

Blend

Using Sampling Plan 1, a single content uniformity result is obtained from each of 12 locations in the V blender, with the following results:

Mean = 97.76; SD = 2.64; RSD (%) = 2.70.

Blend data display

Location		Side	
		Left	Right
Front	Top	100.76	92.53
	Middle	97.17	98.22
	Bottom	95.64	101.91
Back	Top	100.88	98.97
	Middle	97.93	96.30
	Bottom	95.63	97.13

For the tolerance interval approach, the 90% two-sided tolerance interval to capture 96.7% of the individual content uniformity results is $97.76 \pm 3.112(2.64) = (89.54, 105.98)$. Because the interval is completely contained within the 85–115% range, the criterion is met.

The s_{cr} based on the SDPI is $6.25/\sqrt{2.27} = 4.15\%$. Because the standard deviation for the example is 2.64%, which is less than s_{cr} , this sample meets the acceptance criterion.

To use the acceptance limits proposed by Bergum, an acceptance limit table is generated to give the upper bound on the sample RSD for various values of the sample mean. For this example, the table was constructed for content uniformity using a 90% confidence level with a lower bound (LBOUND) of 95%. A portion of the acceptance limit table is as follows:

^aTable entry of interest.

Mean (% claim)	RSD (%)
97.5	3.02
97.6	3.03
97.7	3.05 ^a
97.8	3.07

The sample mean for this example is 97.76%, so the upper limit for the sample RSD is 3.05% (marked with ^a). It is recommended that the means always be rounded to the more restrictive RSD limit so that the assurance level and lower bound specifications are still met. So in this case, 97.76% is rounded to 97.7%. Therefore because the sample RSD of 2.70% is less than the critical RSD of 3.05, the acceptance criterion is met. This means that, with 90% assurance, at least 95% of samples taken from the blender would pass the USP 32 content uniformity test.

Finished Product

Assume that during encapsulation, a sample was taken at each of 30 locations throughout the batch. One capsule from each location was tested for content uniformity and one for dissolution, with the following results:

Mean = 97.63; SD = 2.34;

RSD (%) = 2.40.

Data display

CU				
99.19	96.38	98.82	98.53	94.37
97.33	95.97	101.32	97.78	97.03
97.05	94.39	100.85	97.77	95.42
95.42	96.73	101.29	96.80	103.03
99.23	97.28	97.52	100.26	95.27
97.36	91.77	98.23	98.07	98.35

Mean = 93.84; SD = 3.47; RSD (%) = 3.69.

Data display

Dissolution					
93.78	94.65	87.83	96.81	92.57	87.68
92.17	88.01	96.59	101.46	93.75	99.44
95.27	92.47	98.46	96.34	93.52	90.73
92.75	94.53	88.72	89.58	97.37	96.41
90.93	96.11	93.41	96.60	94.45	92.82

A 90% tolerance interval to capture 96.7% of the individual content uniformity test results is $97.63 \pm 2.625 \times 2.34 = (91.49, 103.77)$. Because this interval is contained within the 85–115% interval, the criterion is met.

Using a criterion based on passing stage 1 of the USP 32 dissolution test, a lower one-sided 90% tolerance interval to capture 99.1% of the individual dissolution values is $93.84 - 2.930(3.47) = 83.67$. Using this criterion, dissolution would fail because the lower bound is less than $Q + 5$, which is 90.

Using a criterion based on stages 2 and 3 of the USP 32 dissolution test, a lower one-sided 90% confidence interval for the population mean is $93.84 - 1.311(3.47)/\sqrt{30} = 93.01$. Because the lower bound on the confidence interval for the mean is greater than Q , these results would pass the criterion.

The Bergum acceptance limit tables for content uniformity and dissolution are as follows:

^aTable entry of interest.

Content uniformity ($n = 30$)

Mean (% claim)	RSD (%)
97.5	3.91
97.6	3.93 ^a
97.7	3.96
97.8	3.98

^aTable entry of interest.

Dissolution ($n = 30$)

Mean (% claim)	RSD (%)
93.6	8.56
93.8	8.61 ^a
94.0	8.66
94.2	8.70

Because the sample RSD values of 2.40% for content uniformity and 3.69% for dissolution are less than the corresponding acceptance limits from the tables of 3.93% and 8.61%, both tests pass the acceptance criterion.

Example 2 (Sampling Plan 2)**Blend**

Two samples are taken from each location in the V blender, with the following results:

Location	Data (% label)		Summary statistics		
	1	2	Mean	Variance	SD
1	96.45	99.19	97.82	3.75	1.93
2	95.90	97.33	96.62	1.02	1.01
3	94.86	99.18	97.02	9.33	3.05
4	96.88	92.55	94.71	9.37	3.06
5	98.40	94.23	96.32	8.69	2.95
6	102.03	102.50	102.27	0.11	0.33
7	93.74	95.36	94.55	1.31	1.15
8	102.43	101.24	101.84	0.71	0.84
9	101.72	97.18	99.45	10.31	3.21
10	97.32	99.64	98.48	2.69	1.64
11	100.58	98.39	99.48	2.40	1.55
12	90.49	94.48	92.49	7.96	2.82

To apply the tolerance interval, SDPI, and Bergum approaches, it is necessary to compute the following variance components:

Variance components	
Source	Estimate (SD)
Between	2.483
Within	2.192
Total	3.312

The estimated standard deviation of a single observation is 3.312.

To use the tolerance interval approach, the Satterthwaite approximate degrees of freedom (df) is 16.82. The 90% tolerance interval to capture 96.7% of the individual capsule content uniformity results is $97.59 \pm 3.111 \times 3.312 = (87.29, 107.89)$. The tolerance factor was determined using linear interpolation. This would meet the criterion because the interval is completely contained within the interval 85–115%.

The s_{cr} using the SDPI is $6.25/\sqrt{2.055} = 4.36$ using the degrees of freedom from the Satterthwaite approximation. The sample standard deviation (3.312) passes this criterion.

The Bergum approach requires calculating the standard deviation of the location means, the within-location standard deviation, and the overall mean:

Mean	97.59
SE (within-location SD)	2.19
Standard deviation of location means	2.93

The standard deviation of location means is computed by taking the standard deviation of the location means. It is not the between-location variance component.

A portion of the acceptance limit table generated to meet the criterion is as follows:

**Table entry of interest.*

Standard deviation of location means

SE	2.8		2.9		3.0	
	LL	UL	LL	UL	LL	UL
2.1	97.6	102.4	98.0	102.0	98.5	101.5
2.2	97.7	102.3	98.1	101.9	98.6	101.4 ^a
2.3	97.8	102.2	98.2	101.8	98.7	101.3

The lower (LL) and upper (UL) acceptance limits for the sample mean are given for various values of the standard deviation of location means and the within-location standard deviation (SE). For our example, after rounding the standard deviation estimates up to the more restrictive values, the combination of 3.0 for the standard deviation of location means and SE of 2.2 is 98.6 to 101.4. Because the mean of 97.59 is not contained in this interval, the criterion fails.

Finished Product

Suppose that four capsules are tested at each of 15 locations throughout the batch for content uniformity and dissolution, with the following results

CU Location	Data (% label)				Summary statistics		
	1	2	3	4	Mean	Variance	SD
1	97.08	99.72	98.37	93.50	97.17	7.13	2.67
2	99.72	100.32	101.01	100.29	100.33	0.28	0.53
3	99.90	98.27	98.88	97.96	98.75	0.73	0.85
4	92.78	92.17	93.44	91.22	92.40	0.89	0.94
5	96.32	96.61	95.66	97.20	96.45	0.42	0.64
6	100.97	102.17	99.06	98.80	100.25	2.57	1.60
7	97.02	95.35	98.65	95.98	96.75	2.08	1.44
8	99.39	98.81	98.63	98.06	98.72	0.30	0.55
9	99.59	97.80	97.67	95.95	97.75	2.21	1.49
10	97.97	98.54	100.26	98.74	98.88	0.96	0.98
11	96.09	97.61	95.49	97.50	96.67	1.10	1.05
12	98.87	97.81	97.28	98.80	98.19	0.60	0.78
13	101.10	102.60	100.48	98.62	100.70	2.71	1.65
14	100.80	100.34	98.49	100.93	100.14	1.27	1.13
15	99.70	100.09	100.14	99.20	99.78	0.19	0.43

A 90% tolerance interval to capture 96.7% of the individual content uniformity results using the Satterthwaite approximation of 21.56 df is $98.20 \pm 2.746 (2.407) = (91.59,$

Variance components		
Source	Mean square	Estimate (SD)
Between	18.486	2.057
Within	1.563	1.250
Total		2.407

104.81). Because the tolerance interval is contained within the 85–115% interval, the tolerance interval indicates that the capsules have good content uniformity.

The descriptive statistics to use the Bergum approach are:

Mean	98.20
SE (within-location SD)	1.25
Standard deviation of location means	2.15

The portion of the table for this combination of results is:

^aTable entry of interest.

Standard deviation of location means						
SE	2.0		2.1		2.2	
	LL	UL	LL	UL	LL	UL
1.2	92.8	107.2	93.2	106.8	93.6	106.4
1.3	92.9	107.1	93.3	106.7	93.7	106.3 ^a
1.4	93.0	107.0	93.4	106.6	93.8	106.2

The lower and upper acceptance limits for the mean are 93.7 to 106.3. Because 98.2 falls within the interval, the capsules pass the acceptance criterion.

Dissolution							
Location	Data (% released)				Summary statistics		
	1	2	3	4	Mean	Variance	SD
1	101.4	99.5	92.9	94.9	97.16	15.55	3.94
2	106.6	101.4	98.0	100.0	101.51	13.53	3.68
3	103.9	100.6	95.3	100.5	100.07	12.64	3.56
4	96.6	93.5	92.6	94.5	94.28	2.89	1.70
5	89.4	93.1	84.6	92.4	89.89	14.97	3.87
6	90.9	90.7	93.2	91.9	91.67	1.39	1.18
7	93.8	92.6	94.8	99.8	95.27	10.08	3.17
8	99.8	98.6	98.1	92.4	97.23	11.03	3.32
9	92.4	96.0	98.4	88.8	93.90	17.86	4.22
10	100.8	99.5	90.6	99.0	97.50	21.50	4.64
11	95.9	98.2	95.9	95.9	96.47	1.39	1.18
12	103.8	103.4	100.8	104.0	102.99	2.28	1.51
13	95.2	92.2	96.1	94.2	94.43	2.88	1.70
14	96.4	98.7	95.4	101.7	98.03	7.69	2.77
15	95.7	96.7	96.2	95.9	96.13	0.17	0.41

Variance components		
Source	Mean square	Estimate (SD)
Between	48.253	3.130
Within	9.056	3.009
Total		4.342

A 90% one-sided tolerance interval to capture 99.1% of the individual dissolution values using the Satterthwaite approximation of 31.13 *df* is $96.44 - 2.907(4.342) = 83.82$. The tolerance interval indicates that the capsules are not assured of passing stage 1 of the USP 32 dissolution test. The confidence interval approach based on stages 2 and 3 of the USP 32 dissolution test has a lower bound for the population mean of $96.44 - 1.345\sqrt{48.25/\sqrt{60}} = 95.23$. Because the lower bound of 95.23 is greater than the *Q* of 85%, the criterion is met.

Using the Bergum approach, the descriptive statistics are

Mean	96.44
SE (within-location SD)	3.01
Standard deviation of location means	3.47

The portion of the acceptance limit table for this combination of results is:

^aTable entry of interest.

Standard deviation of location means			
SE	3.25	3.50	3.75
2.75	88.80	89.10	89.40
3.00	88.90	89.10	89.40
3.25	88.90	89.20 ^a	89.40

The lower acceptance limit for the mean is 89.20%. Because 96.44 is greater than 89.20, the capsules pass the acceptance criterion for dissolution.

Both the blend and final capsules passed content uniformity. Therefore, it is not necessary to perform the Analysis by Synthesis approach given in the PDA paper.^[18]

CONCLUSION

A number of statistical techniques are described for possible use in the analysis of prospective process validation data of tablets and capsules and some of their advantages and disadvantages are discussed. Detailed examples are provided to aid in the understanding of many of the techniques discussed. The authors hope that this entry will stimulate the use of the outlined statistical approaches for the analysis of validation data by industry and their acceptance by the FDA. For powder blends, industry feels compelled to use the FDA approach as it is most likely to be accepted by the FDA. However, a

number of other approaches, such as the SDPI and the Bergum approaches are also more constraining than the USP 32 test while providing a sound statistical basis for the development of acceptance criteria. For finished product testing of content uniformity and dissolution, the Bergum approach offers a number of advantages that the authors believe should be considered. It is hoped that this entry will not only encourage an increase in the use of statistical techniques for the analysis of validation data but also spur discussion of the relative merits of the various techniques.

Abstract

This entry describes the study design and bioequivalence criteria of particle size distribution for both nonprofile and profile analysis, and offers some statistical issues as well as simulated results in an example study for further illustration.

Keywords: Bioequivalence; Compositional data; In vitro test; Particle; Size distribution; Profile analysis.

INTRODUCTION

For some locally acting drug products, such as nasal aerosols and nasal sprays, bioavailability (BA) and bioequivalence (BE) assessments are complicated because delivery to the sites of action does not occur primarily after the systemic absorption. Although BA and BE studies for nasal aerosols and nasal sprays generally would consider both local delivery and systemic absorption, the study of the former is of primary importance. *In vitro* studies, which refer to the studies outside the living organism, are performed to evaluate the local delivery. According to a recent guidance for BA and BE studies for nasal aerosols and nasal sprays for local action issued by the U.S. Food and Drug Administration (FDA)^[1] in April 2003, *in vitro* BE studies are usually characterized by the following seven tests: (i) single actuation content through container life; (ii) droplet size distribution by laser diffraction; (iii) drug in small particles/droplets, or particle/droplet size distribution by cascade impactor (CI); (iv) drug particle size distribution by microscopy; (v) spray pattern; (vi) plume geometry; and (vii) priming and repriming. Detailed descriptions regarding purposes and requirements of the above tests can be found in^[1] and the entry of *In vitro* Bioequivalence Testing in this encyclopedia (Wang, et al.^[2]). The FDA^[1] recommends non-profile analysis be applied to study the content uniformity through container life, droplet size distribution, spray pattern, and priming and/or repriming, while the profile analysis be applied to the study of particle/droplet distribution by cascade impactor. The major difference between a nonprofile analysis and a profile analysis is that the data for nonprofile analysis are usually *independent* while the data for profile analysis are correlated. Although the CI profile data can be viewed as

growth curve data, due to special features described later in this entry, the usual parametric or non-parametric growth curve analysis methods can not be directly applied. There had been little literature available regarding the analysis of the CI profile data until the publication of a 1999 FDA guidance on *in vitro* bioequivalence testing for nasal aerosols and nasal sprays products (FDA^[3]). In this entry, we discuss the existing testing procedures for establishment of BE with CI profile data. For illustration and comparison purpose, we focus on droplet/particle size distribution test by cascade impactor (CI).

Study designs and BE criteria of particle size distribution (PSD) for both the nonprofile and profile analysis are described and compared in the section “Study Designs and BE criteria.” In the section “Testing Procedures for Profile Analysis,” statistical issues for assessment of BE based on PSD are discussed and two testing procedures are introduced. Simulation results and an example concerning *in vitro* test for PSD are provided to illustrate the two testing procedures in the section “Simulation Study and an Example.” A parametric method based on the additive logistic normal model is proposed in the section “Model-based Testing Methods” as an alternative approach, followed by a brief discussion in the last section.

STUDY DESIGNS AND BE CRITERIA

In pharmaceutical practice, PSD is an important factor for development of nasal aerosols and nasal sprays drug products since the sizes of particles/droplets by multistage cascade impactor (CI) are useful measurements of aerodynamic diameter based on inertial impaction, which is an important factor in the deposition of drug in the nasal

passages. The multi-stage CI used in the study is necessarily specified in order to minimize distortion and to ensure reproducibility. To ensure consistency of *in vitro* performance, the FDA^[1] recommends that at least three batches (or sublots) of each of the test (T) and reference (R) drug products be used. Although not stated in the recent FDA guidance, at least 10 containers (canisters or bottles) is usually considered. For each selected container, CI data are only required at the beginning lifestage and the number of actuations are kept to the minimum (generally no more than 10) for an accurate and reliable assessment. Depositions at different stages for each actuation are usually reported in mass unit. Let X_s be the deposition in mass unit at stage s , where $s = 1, \dots, S$. Then, data can be expressed as S -dimensional vector $X = (X_1, \dots, X_S)$. Depending on whether the study is for aerosol or spray, X can be used in different ways.

For nasal sprays drug products, small droplets/particles, defined as being smaller in diameter than the effective cut-off diameter of the top stage of the CI, are of main interest since they may be potentially delivered to the regions beyond the nose and thus cause a safety concern. For this reason, the total number of stage S may be chosen as $S = 2$. Let X_1 be the mass deposition at the top stage, and X_2 be the pooled mass of all the CI stages below the top stage, then the nonprofile analysis use only X_2 for each actuation. For simplicity, we denote X_2 as Y . For BE study, let Y_T, Y_R , and Y'_R be the pooled mass depositions at the below-the-top stages for one actuation of one test and two references canisters, then *in vitro* BE can be claimed if the following hypothesis is rejected.

$$H_0: \theta = \frac{E(Y_T - Y_R)^2 - E(Y_R - Y'_R)^2}{\max\{\sigma_0^2, E(Y_R - Y'_R)/2\}} \geq \theta_{BE}, \quad (1)$$

where σ_0^2 is a prespecified constant and θ_{BE} is the BE limit, which is based on the prior judgment and may be adjusted by the reference drug. Testing procedures based on confidence intervals have been developed. In its earlier draft guidance, FDA recommends a test proposed by Hyslop, Hsuan, and Holder^[4] (FDA^[3]). When replicates are available, Chow, Shao, and Wang^[5] provide an asymptotic test based on the linear mixed-effects model to address the within-canister and between-canister variations. The procedure proposed by Chow, Shao, and Wang^[5] is more consistent with the study design recommended by FDA.^[1] Both methods are based on normal assumption. For a general discussion of *in vitro* nonprofile BE tests, see Chow and Shao.^[6] For nasal sprays drug products, the profile analysis of BE assessment involves comparison of the profiles between the test and reference drug products. According to FDA,^[3] the profile of the PSD $X = (X_1, X_2)$ is defined as

$$p = (p_1, p_2) = \left(\frac{X_1}{X_1 + X_2}, \frac{X_2}{X_1 + X_2} \right).$$

The profile data p_1 and p_2 are correlated in a complicated way.

Unlike nasal sprays drug products in which the pooled mass of drug deposition below the top stage is of interest, the CI studies of nasal aerosols PSD focus completely on the profiles and nonprofile analysis is not required. For assessment of BE based on USP 25 Apparatus 1 (< 601 >), the FDA^[1] recommends determination of profiles based on depositions at 11 sites: (i) sum of valve stem plus actuator; (ii) induction port; (iii—x) eight individual stages; and (xi) filter. Again, deposition should be reported in mass unit. For nasal aerosols drug products, the total number of profile stages S is suggested to be at least 3.

To set up a BE criterion for CI profile data, a reasonable measure of profile distance should be determined first. The BE criterion under thus a measure should be able to calibrate the relative mean difference normalized/adjusted by the within-container and between-container variations at *each* profile stage (not the CI physical stage since the depositions at several CI stages could be combined). One possible choice of such a measure is the one suggested by the FDA.^[3] Let

$$p_T = (p_{T1}, p_{TS}), \quad \text{and} \quad p_R = (p_{R1}, p_{RS}),$$

be the profiles of a test drug and a reference drug, respectively, then their profile difference is defined as

$$d(T, R) = \sum_{s=1}^S \frac{(p_{Ts} - p_{Rs})^2}{(p_{Ts} + p_{Rs})/2},$$

and $d(R, R')$ can be defined similarly for any two reference profiles. The BE criterion given by FDA^[3] is based on a triplet (T, R, R') , formed by one test and two reference drugs. Denote $R + R'/2$ as the component-wise average of the two reference drug profiles, and define

$$rd = \frac{d\left(T, \frac{R + R'}{2}\right)}{d(R, R')}, \quad (2)$$

then the profile BE measure suggested by the FDA^[3] is $Rd = E(rd)$. The CI profile BE is established if the following hypothesis is rejected at the 5% level of significance

$$H_0: Rd \geq \theta_{BE}. \quad (3)$$

TESTING PROCEDURES FOR PROFILE ANALYSIS

As mentioned in the previous section, the study design for CI profile BE assessment usually consists of 3 lots from the test drug, 3 lots from the reference drug, and at least 10 canisters from each lot. Thus, a total of 60 canisters are

tested and profile vectors are observed. CI profile data are complicated in several aspects. First, the data are highly correlated. Second, the data are not normally distributed. In fact, it may be hard to characterize its distribution parametrically. Finally, due to limited data, which are highly correlated, asymptotic methods may not be applicable. For these reasons, model independent finite sample testing procedures are preferred. In what follows, we will introduce two finite sample approaches.

The FDA's Approach

To test (3), the FDA^[3] suggests a bootstrap type approach to estimate the 95% confidence upper limit of Rd. To obtain this upper limit, the six lots used in the study are matched into different combinations of lot-triplets, each of which contains one test lot and two different reference lots. Within each lot-triplet, the 30 canisters are matched into different combinations of canister-triplets, each of which contains one test canister and two reference canisters from different lots. A random sample of 500 canister-triplets are then selected from the population of all possible different canister-triplets. Let rd_i be the ratio in (2) computed based on the i th canister-triplet in the random sample, $i = 1, \dots, 500$, and $\overline{Rd}_{95}$ be the 95th percentile of $rd_1, \dots, rd_{500}$. Then $\overline{Rd}_{95}$ is used as a 95% upper bound of Rd and is recommended for testing (3). The BE limit θ_{BE} , which is not discussed in either FDA^[3] or FDA,^[1] has to be determined by simulations.

There are several major concerns for this approach. First, Rd may not be well defined, especially when the reference profiles are uniform or follow a compound multinomial distribution as speculated by the FDA.^[3] Second, even if Rd is well defined, rd_i is not an accurate estimator of Rd since it is based on one triplet. Consequently, $\overline{Rd}_{95}$ can not be expected to be a 95% upper bound for Rd. This point will be illustrated in the section "Simulation Study and an Example." Finally, although the FDA approach looks like either a bootstrap approach or a randomized test approach, neither approach is statistically justified since the different lot-triplets share at least one common reference lot and the rd values are neither independent nor identically distributed.

Some modification could be made to the FDA approach. First, instead of defining Rd as the mean of rd, we could define it as a certain percentile of rd. Second, instead of using one single triplet, we could use the mean of m independent triplets to compute rd_i . That is, let $\bar{T}$, $\bar{R}$, and $\bar{R}'$ be the component-wise sample means of m independent canister-triplet profiles for the test and two reference drug products, respectively, then

$$rd_i = \frac{d\left(\bar{T}, \frac{\bar{R} + \bar{R}'}{2}\right)}{d(\bar{R}, \bar{R}')} \quad (4)$$

Although after modification of the definition of Rd, the FDA BE criterion can still be valid, the validity of the FDA approach has not been statistically justified even the new rd_i in (4) is used.

Two-stage Random Sampling Approach

As noted in the previous section, the BE profile distance measure Rd suggested by the FDA^[3] may not be well defined. A modification of the definition of Rd may be made, as suggested by Cheng and Shao.^[7] Instead of defining Rd as the mean of rd, Cheng and Shao^[7] defined it as a certain percentile of rd. Along this line, a simple testing procedure is proposed. For illustration purpose, consider the case where Rd is the median of rd.

Cheng and Shao's method is based on a two-stage sampling procedure and therefore it is referred to as a two-stage random sampling (TRS) method. At the first stage, a lot-triplet is randomly selected with replacement from the nine possible lot-triplets given. At the second stage, for any sampled lot-triplet, one canister is randomly selected from each lot and rd is calculated. This process is repeated independently n times to produce independent and identically distributed $rd_1, \dots, rd_n$. Let F be the cumulative distribution function of rd_j and Rd be the median of F . Then, (3) is equivalent to

$$H_0 : 0.5 \geq F(\theta_{BE}). \quad (5)$$

Let Y be the number of rd_j 's $\leq \theta_{BE}$. Then Y has a binomial distribution with size n and probability $F(\theta_{BE})$. A level α test for (5) rejects H_0 if and only if $Y > b_{n,\alpha}$, where $b_{n,\alpha}$ is an integer satisfying

$$\sum_{k=0}^{b_{n,\alpha}} \binom{n}{k} \frac{1}{2^n} = 1 - \alpha, \quad (6)$$

and α is a positive number that is close to 5%. If $n = 18$, for example, we may take $\alpha = 0.0481$, which gives $b_{n,\alpha} = 12$. That is, the bioequivalence can be claimed with 95.19% statistical assurance when at least 12 of 18 canister-triplets have the rd values $\leq \theta_{BE}$. Note that this test procedure ensures that the level of the test is exactly α .

Since sampling of lot-triplets is random in this procedure, the actual number of sampled canisters from each lot (or lot-triplet) is random, which may not be practically appealing. This is also true for the FDA's procedure. Although 10 canisters are sampled from each lot in the FDA's bootstrap-type procedure, the number of canisters from each lot (or lot-triplet) is still random in the 500 randomly selected canister-triplets. To use a more balanced sampling design, the following modification is also considered by Cheng and Shao.^[7] Assume that in each test lot we sample $3k$ canisters and in each reference lot we sample $6k$ canisters. Then, we randomly group these canisters into

9k non-overlapped canister-triplets, with one test canister and two reference canisters from different lots in each canister-triplet. The rd value of each canister-triplet is calculated, which results in $rd_1, \dots, rd_{9k}$. Note that these rd values are identically distributed, but are slightly dependent. Let Z be the number of rd_j 's $\leq \theta_{BE}$. Then Z is *not* exactly binomial, but is close to binomial. If we still reject the null hypothesis H_0 in (5) when $Z > b_{n,\alpha}$, where $b_{n,\alpha}$ is defined by (6), then the test should be approximately of level α . Simulation shows that this second method (which can be called a random grouping method) has only a slightly inflated size. This method, however, is more balanced.

SIMULATION STUDY AND AN EXAMPLE

To evaluate the performances of the procedures described in this entry, two simulations studies were conducted by Cheng and Shao.^[7] The first simulation was to study the behavior of the FDA's procedure, while the second simulation was to study the properties of the TRS method. In the first simulation, it is assumed that the number of stage $S = 3$. Let $(M_{kj1}, M_{kj2}, M_{kj3})$ be a random vector distributed as multinomial $(100, P_{kj1}, P_{kj2}, P_{kj3})$, and ε_{kji} 's be independent random errors having gamma distributions with mean 1 and variances σ_k^2 , where $j (= 1, 2, 3)$ is the index for lots, $k (= T, R)$ is the index for test or reference, and ε_{kji} 's and M_{kji} 's are independent. The profile vectors are given by

$$(X_{kj1}, X_{kj2}, X_{kj3}) = (\varepsilon_{kj1} M_{kj1}, \varepsilon_{kj2} M_{kj2}, \varepsilon_{kj3} M_{kj3}).$$

The values of P_{kji} were obtained from estimates in a real data set:

$$\begin{aligned}(P_{T11}, P_{T12}, P_{T13}) &= (0.99735, 0.00235, 0.00030) \\(P_{T21}, P_{T22}, P_{T23}) &= (0.99780, 0.00150, 0.00070) \\(P_{T31}, P_{T32}, P_{T33}) &= (0.99670, 0.00285, 0.00045) \\(P_{R11}, P_{R12}, P_{R13}) &= (0.99805, 0.00170, 0.00025) \\(P_{R31}, P_{R32}, P_{R33}) &= (0.99675, 0.00240, 0.00085)\end{aligned}$$

Four different values of (σ_T, σ_R) were considered:

$$(0.05, 0.05), (0.05, 0.10), (0.10, 0.05), (0.10, 0.10).$$

For each fixed value of (σ_T, σ_R) , the random variable rd is defined according to (2) with the triplet T, R, R' randomly selected from the following nine possible of lot-triplets:

$$\begin{array}{lll}T1, R1, R2 & T1, R1, R3 & T1, R2, R3 \\T2, R1, R2 & T2, R1, R3 & T2, R2, R3 \\T3, R1, R2 & T3, R1, R3 & T3, R2, R3\end{array}$$

Table 1 lists the median rd_{50} and 95th percentile rd_{95} of rd for each value of (σ_T, σ_R) based on 10,000,000 simulations. Also included in Table 1 are simulation proportions of $\overline{Rd}_{95} < \text{the median}$, 2, or the 95th percentile based on 5,000 simulations.

When rd_{50} is considered as the parameter Rd, $P(\overline{Rd}_{95} < rd_{50})$ reported in Table 1 is a type I error probability of FDA's test procedure if $\theta_{BE} = rd_{50}$, whereas $P(\overline{Rd}_{95} < 2)$ in Table 1 is a value of the power of the FDA's test. Since all values of the median are substantially smaller than 2, the result in Table 1 indicates that the FDA's test is very conservative. On the other hand, when rd_{95} is considered as the Rd in Table 1 and $\theta_{BE} = rd_{95}$, $P(\overline{Rd}_{95} < rd_{95})$ in Table 1 is a type I error probability of FDA's test and the result in Table 1 shows that FDA's procedure is incorrect and too liberal. Even if $\overline{Rd}_{95}$ is viewed as an estimator of rd_{95} , it is an incorrect estimator since $P(\overline{Rd}_{95} < rd_{95})$ may be far away from 0.5, for example, in the cases where $(\sigma_T, \sigma_R) = (0.05, 0.10)$ and $(\sigma_T, \sigma_R) = (0.10, 0.05)$.

As indicated in Cheng and Shao,^[7] the second simulation was done to study the properties of the TRS method. In the second simulation, similar settings were considered. That is, $n = 18(b_{n,\alpha} = 12)$ two-stage random samples of rd are considered, since this leads to a total of 54 canisters, which is close to the total of 60 canisters in FDA's procedure. Results based on 5,000 simulations are given in Table 2.

From Table 2, when θ_{BE} is chosen to be the median of rd (given in Table 1), the probabilities in Table 2 are type I error probabilities. The nominal value is $\alpha = 0.0481(n = 18)$. Hence, the results in Table 2 are within the nominal value $\pm 0.006 = \pm 2$ estimated standard simulation error. When $\theta_{BE} = 1, 1.5$, or 2, the results in Table 2 are values of power except for the case where $\theta_{BE} = 1$ and $(\sigma_T, \sigma_R) = (0.10, 0.05)$. It can be seen that a reasonable power can be achieved when θ_{BE} is substantially larger than

Table 1 Simulation Results for FDA's Upper Bound $\overline{Rd}_{95}$

	(σ_T, σ_R)			
	(0.05, 0.05)	(0.05, 0.10)	(0.10, 0.05)	(0.10, 0.10)
rd_{50}	0.6753	0.5378	1.3305	0.7684
rd_{95}	117.3226	44.1099	230.5589	70.3797
$P(\overline{Rd}_{95} < rd_{50})$	0	0	0	0

$P(\overline{Rd}_{95} < rd_{95})$	0.5628	0.0908	0.9626	0.5368

Table 2 Simulation Results on the Rejection Probability for the TRS Method

θ_{BE}	(σ_T, σ_R)			
	(0.05, 0.05)	(0.05, 0.10)	(0.10, 0.05)	(0.10, 0.10)
rd ₅₀	0.0494	0.0460	0.0538	0.0508
1.0	0.1748	0.3760	0.0132	0.1248
1.5	0.3596	0.6340	0.0752	0.3646
2.0	0.4842	0.7942	0.1560	0.5556

the true median of rd or the test variability σ_T^2 is smaller than the reference variability σ_R^2 .

Example

An *in vitro* BE profile study for nasal solutions was conducted to compare the test drug and the generic drug (reference). Three lots were selected for both the test solution and the reference solution. Within each lot, 18 canisters were drawn and their profiles at the three stages were recorded. A summary of the profile data is given in Table 3.

If we choose $\theta_{BE} = 2$, then for the TRS method, statistic Y defined in §3.2 is $Y = 13$. Therefore, the null hypothesis in (5), or (3) is rejected and the *in vitro* BE is claimed. For the FDA method, formula (4) with $m = 100$ is used to compute the rd's, the resulting 95% percentile is $\overline{\text{Rd}}_{95} = 270.94$, which is much larger than $\theta_{BE} = 2$. This example shows that the FDA method is both unstable and too conservative.

MODEL-BASED TESTING METHODS

For any profile $\mathbf{p} = (p_1, \dots, p_S)$, there is a sum-to-one constraint on its components, that is $p_1 + \dots + p_S = 1$ and $p_s > 0, s = 1, \dots, S$. This imposes a statistical challenge to the modeling and analysis of profile data. It is clear that neither one of the two methods described in the section “Testing Procedures For Profile Analysis” takes this constraint into consideration. In this section, we discuss some alternative testing methods based on modeling of this special type of data.

In view of the sum-to-one constraint for the profile data, one immediate choice for its distribution is a Dirichlet Model. However, the covariance matrix of a Dirichlet distribution has a special structure, which implies that it may not be too restrictive to model the profile data via Dirichlet distribution. On the other hand, it turns out that profile

data also arise in many other areas, particularly in geology, where such type of data is termed as “compositional data.” There is an extensive literature on statistical methods for compositional data. The most influential method, the logistic normal method proposed by Aitchison,^[8] will be described below. Other methods include generalized Liouville method by Rayens and Srinivasan,^[9] and the Bayesian method by Iyengar and Dey.^[10]

We adopt the logistic normal method for its simplicity, maturity, and wide applications. The method is based on the following additive log ratio transformation of the compositional data

$$\mathbf{y} = \left(\log \frac{p_1}{p_S}, \dots, \log \frac{p_{S^*}}{p_S} \right),$$

where $S^* = S - 1$. A profile vector $\mathbf{p}$ is said to have an additive logistic normal distribution, denoted as $\mathbf{p} \sim L_{S^*}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, if $\mathbf{y} \sim N_{S^*}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, an S^* -dimensional normal distribution with mean $\boldsymbol{\mu}$ and covariance $\boldsymbol{\Sigma}$. It can be proved that if a deposition vector $\mathbf{X} = (X_1, \dots, X_S)$ has a multivariate log-normal distribution, then $\mathbf{p}$ has an additive logistic normal distribution (Aitchison^[11]).

Let $\mathbf{p}_{Ti}$ be the profile of the i th subject in the treatment group and $\mathbf{p}_{Ri}$ be the i th subject in the treatment group, $i = 1, \dots, n$. We consider the following model

$$\begin{aligned} \mathbf{p}_{T1}, \dots, \mathbf{p}_{Tn} &\sim L_{S^*}(\boldsymbol{\mu}_T, \boldsymbol{\Sigma}_T), \\ \mathbf{p}_{R1}, \dots, \mathbf{p}_{Rn} &\sim L_{S^*}(\boldsymbol{\mu}_R, \boldsymbol{\Sigma}_R). \end{aligned} \quad (7)$$

Here we assume equal sample sizes for the two groups but allow $\boldsymbol{\Sigma}_T \neq \boldsymbol{\Sigma}_R$. A nature choice of BE measure is

$$\theta = (\boldsymbol{\mu}_T - \boldsymbol{\mu}_R)'(\boldsymbol{\Sigma}_T + \boldsymbol{\Sigma}_R)^{-1}(\boldsymbol{\mu}_T - \boldsymbol{\mu}_R),$$

based on which the profile BE hypothesis can be formulated as

$$H_0: \theta \leq \theta_{BE}, \quad (8)$$

where θ_{BE} is a prespecified BE limit. Here we briefly describe the testing method for (8). Further detail is provided in Cheng.^[12] Let $\bar{\mathbf{Y}}_T, \bar{\mathbf{S}}_T$ be the sample mean and sample covariance of $\mathbf{y}_{Ti}$'s, the additive log ratio transformation of $\mathbf{p}_{Ti}$'s, respectively. Define

$$T^2 = n(\bar{\mathbf{y}}_T - \bar{\mathbf{y}}_R)'(\mathbf{S}_T + \mathbf{S}_R)^{-1}(\bar{\mathbf{y}}_T - \bar{\mathbf{y}}_R).$$

Table 3 Summary of Profile Data for Test and Reference Nasal Solutions

	Overall mean profile	Within canister standard deviation	Between canister standard deviation
Test	(0.9983, 0.0010, 0.0007)	0.0011	0.0014
Reference	(0.9942, 0.0042, 0.0016)	0.0012	0.0016

It is easily shown that T^2 is asymptotically distributed as $\chi^2_{S^*}(n\theta)$, a non-central chi-square distribution with S^* degrees of freedom and noncentrality parameter $n\theta$. Thus, the test which rejects H_0 in (8) if $T^2 > \chi^2_{S^*,\alpha}(n\theta_{BE})$ is an asymptotically level α test, where $\chi^2_{S^*,\alpha}(n\theta_{BE})$ is the $(1-\alpha)$ th percentile of $\chi^2_{S^*,\alpha}(n\theta_{BE})$. Under further assumption that $\Sigma_T = \Sigma_R$, we have

$$\frac{2(n-S^*)}{(n-1)S^*}T^2 \sim F_{S^*, 2(n-S^*)}(n\theta),$$

a noncentral F-distribution with $(S^*, 2(n-S^*))$ degrees of freedom and non-centrality parameter $n\theta$. An exact test for (8) can be derived easily.

Some quick remarks are in order. First, this new transformation approach is consistent with methods used in other fields where compositional data arise. The new BE criterion is easier to interpret and incorporates the variance information. Second, the new test is based on large sample theory hence is robust. Third, other BE measures/criteria can also be utilized under model (7). For example, we could define BE measure as

$$\theta = (\mu_T - \mu_R)' \Sigma_R^{-1} (\mu_T - \mu_R) + \text{tr}(\Sigma_R^{-1/2} \Sigma_T \Sigma_R^{-1/2} - I)$$

and the corresponding test can be derived using the δ -method. This BE measure is analogous to the following nonprofile BE measure suggested by FDA for univariate responses

$$\frac{(\mu_T - \mu_R)^2}{\sigma_R^2} + \frac{(\sigma_R^2 - \sigma_T^2)}{\sigma_R^2}.$$

Finally, we may jointly model the total deposition $W = \sum_{s=1}^S X_s$ and the profile $\mathbf{p}$ as $(\log W, \mathbf{y})' \sim N_S(\tilde{\mu}, \tilde{\Sigma})$. This endeavor is relevant since the total deposition may also be important in establishing the *in vitro* BE.

DISCUSSION

Both of the approaches discussed in the section “Testing Procedures For Profile Analysis” are non-parametric approach. The major differences between the TRS method and the FDA method include (i) the TRS method produces independent, identically distributed rd values; while the rd values in the FDA method are dependent, and (ii) for a given total number of non-overlapping canister triplets, the FDA method is more computationally intensive.

It should be noted that a chi-square type measure is adopted by both methods. Other measures may also be

used to formulate a BE criterion. Other possible choices of profile distance measures discussed in Tsong, Sathe, and Shah^[13] may be considered.

Although nonparametric methods are generally preferred for the CI profile BE study, it is more convenient to model the PSD profile parametrically. In the section “Model-Based Testing Methods,” we provide one such method which is both easy to interpret and implement. Since the asymptotic test derived in section “Model-Based Testing Methods” is still valid even if the assumption in (7) fails to hold, the method should be considered as robust and nonparametric in nature. Finally, we point out that profile data can also be modeled semiparametrically using a quasi-likelihood approach (Cheng^[12]).

Propensity Score Analysis and Its Application in Regulatory Settings

Lilly Q. Yue

Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

Propensity score analysis is a versatile statistical method for causal inference in observational studies. This entry provides the equation for determining propensity score and details the procedure of this type of analysis.

INTRODUCTION

First introduced by Rosenbaum and Rubin,^[1] the propensity score $e(X)$ for a subject with a vector X of observed covariates is the conditional probability of receiving treatment ($Z = 1$) rather than control ($Z = 0$) given X :

$$e(X) = \Pr(Z = 1 | X) \quad (1)$$

Propensity score analysis is a versatile statistical method for causal inference in observational studies that can improve treatment comparison by adjusting for up to a relatively large number of potentially confounding covariates.^[1–3] In recent years, there has been an increased interest in applying this methodology to non-randomized clinical studies,^[4–6] including those designed to support regulatory applications for marketing medical products.

The propensity score $e(X)$ is a balancing score in the sense that it is a function of the observed covariates X such that the conditional distribution of X given $e(X)$ is the same for subjects in the treatment group and subjects in the control group.^[1] If treatment assignment is strongly ignorable, that is, the treatment assignment Z and the potential outcome Y are conditionally independent given the observed covariates, X , i.e., $\Pr(Z | X, Y) = \Pr(Z | X)$, and if $0 < \Pr(e(X)) < 1$, for all X , then the average treatment effect at each value of the propensity score is an unbiased estimate of the true treatment effect at that propensity score.^[1] The above assumption requires that all covariates relevant to both treatment assignment and potential outcomes are measured (i.e., there is no hidden bias). In practice, the propensity score is estimated by modeling the probability of treatment group membership as a function of the observed baseline covariates via, for example, a multiple logistic regression or discriminant analysis. Propensity score matching, stratification, weighting, covariate adjustment, and some combination of those strategies can then

be used to produce unbiased estimates of the treatment effect (Refs. [1–3; 7–15] and references therein).

Rubin^[7] points out that as a balancing score, the propensity score is a one-dimensional summary of the observed covariates such that when the propensity scores are balanced across two treatment groups, the distribution of all the covariates are balanced in expectation across the two groups. Therefore, evaluating treatment-group overlap in terms of the distributions of propensity scores provides a straightforward assessment of whether the two treatment groups are sufficiently similar with respect to baseline covariates to allow a sensible treatment comparison. When sufficient overlap is present, the propensity score analysis can provide a straightforward treatment comparison that reflects adjustment for differences in all observed baseline covariates. Otherwise, as indicated by Rubin,^[7] either the propensity score prediction model would need to be reformulated or it would have to be concluded that the covariate distributions did not overlap sufficiently to allow propensity score analysis to adjust for these covariates. Therefore, in a regulatory environment, it is crucial to start with comparable patient populations, because propensity score analysis does not work well (in fact, no statistical method works well) when there is serious imbalance in baseline covariates between the two treatment groups. Unfortunately, it is sometimes impossible to predict in advance whether the patient population with a new treatment is comparable to that with a control, which is a risk that must be taken into consideration. In fact, an unsuccessful non-randomized study can be more burdensome than a randomized trial at the outset.^[16,17]

Like other covariate adjustment methods, propensity score methods can only adjust for observed covariates and not for unobserved ones. This is always a limitation of non-randomized studies compared with randomized trials where randomization tends to balance both observed and unobserved covariates. Therefore, some sensitivity analysis for hidden bias is often desirable in a medical product regulatory

submission based on a non-randomized study. It should also be noted that propensity score methods may not eliminate all the bias resulting from imbalance in the observed covariates, due to the limitation of propensity score modeling, which typically uses a linear combination of covariates.^[7]

Braitman and Rosenbaum^[10] state that the propensity score methods work better under three conditions: (i) when clinical outcome event is rare, (ii) when there are a large number of patients in each treatment group, and (iii) when there are many covariates measured. In a regulatory setting, it may be inappropriate to conduct propensity score analysis when sample size is small, which could result in some propensity score subclasses, such as quintiles, containing patients from only one treatment group, and the inappropriate exclusion of these patients from the data analysis.^[16] Furthermore, although it is expected that all observed covariates could be balanced between the two treatment groups by propensity scores, in a small non-randomized study, substantial imbalance of some covariates might be unavoidable despite the use of a sensible propensity score method. It is essential to collect a rich set of clinically relevant baseline covariates that are potentially related to both the treatment assignment and the clinical outcomes.^[15] These covariates should be well measured in the study and used in the data analysis.

Rubin^[9] emphasizes the importance of designing of observational studies prospectively and advocates that observational studies can and should be designed to approximate randomized experiment as closely as possible without any access to any outcome data, thereby assuring the objectivity of the design. Particularly in a regulatory environment, the prospective design of a non-randomized confirmatory study with propensity score analysis specified as primary analysis is essential, in order to provide valid and convincing evidence of safety and effectiveness of a medical product.^[16,17] As discussed above, it is crucial to select comparable patient populations, as no statistical method works well when there is severe imbalance in baseline covariates between the two treatment groups. In the study protocol, details of the propensity score data analysis need to be pre-specified, including the propensity score method, for example, stratification, missing-data handling strategy for baseline covariates, and sample size estimation in the context of propensity scores, as propensity score adjustment may be sensitive to these factors.^[12,18] It is also important to pre-specify all clinically relevant baseline covariates, collect them in the study, and use them in the data analysis. At the same time, sensitivity analysis should be planned to take into consideration unobserved covariates. Furthermore, the assessment of the success of the propensity score estimation should be performed by checking the resulting balance of the distributions of covariates after propensity score adjustment, using Rubin's^[8] balance criteria or Rosenbaum and Rubin's^[2] balance criteria. In addition, the evaluation of treatment group comparability with respect to the distribution of baseline covariates should be conducted by assessing treatment group balance in terms of the distribution of propensity scores.

Propensity Score: Methodology and Application to Clinical Studies

Lilly Q. Yue and Heng Li

Division of Biostatistics, Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

Formulated by Rosenbaum and Rubin, the propensity score methodology is a versatile statistical technique used mainly in observational (non-randomized) studies for improving treatment comparison by adjusting for up to a relatively large number of potentially confounding covariates in estimating the effect of treatments on outcomes. Since its formulation, the methodology has been widely used in areas such as epidemiological and social science studies. There has been an increased interest in applying this methodology to non-randomized clinical studies, including those designed to support regulatory applications for marketing medical products. This entry gives a brief overview of propensity score methods and discusses important things to consider in the application of these methods in clinical studies, especially those submitted for regulatory review.

Keywords: Propensity score; Matching; Stratification; Weighting; Observational study.

INTRODUCTION

First introduced by Rosenbaum and Rubin,^[1] the propensity score $e(X)$ for a subject with a vector X of observed baseline covariates is the conditional probability of receiving treatment ($Z = 1$) rather than control ($Z = 0$), given X : $e(X) = \Pr(Z = 1 | X)$. The propensity score $e(X)$ is a balancing score in the sense that for subjects with the same propensity score, the distribution of observed covariates is the same between the treated group and the control group. If treatment assignment is strongly ignorable, that is, the treatment assignment Z and the potential outcome Y are conditionally independent, given the observed covariates, X , i.e., $\Pr(Z | X, Y) = \Pr(Z | X)$, and if $0 < e(X) < 1$, for all X , then the average treatment effect on outcome at each value of the propensity score is an unbiased estimate of the true treatment effect at that value of propensity score.^[1] The above assumption requires that all covariates relevant to both treatment assignment and outcome are measured and captured in X (i.e., there is no hidden bias). In practice, the propensity score is estimated by modeling the probability of treatment group membership as a function of the observed covariates, typically via logistic regression.

PROPENSITY SCORE METHODOLOGY

Propensity score methodology refers to a collection of versatile statistical tools for causal inference in observational

studies based on the concept of propensity score.^[1–12] Commonly used propensity score methods include propensity score matching, stratification (subclassification) on the propensity score, inverse probability of treatment weighting (IPTW) using the propensity score, covariate adjustment using the propensity score, and some combinations of these approaches.^{[1–8][10–17]} The propensity score methods could be used to design and analyze an observational study, mimicking some of the characteristics of a randomized controlled trial.^[13] Although the first three of the aforementioned methods enable the separation of the design and the analysis, an appealing feature that is critical in clinical studies submitted for regulatory review, covariate adjustment using the propensity score does not enable such separation.

Like other covariate adjustment methods, propensity score methods can only adjust for observed covariates and not for unobserved ones. The impossibility of adjusting for unobserved covariates is a fundamental limitation of non-randomized studies that contrasts them with randomized trials where randomization tends to balance both observed and unobserved covariates. Therefore, some sensitivity analysis for hidden bias is often desirable in a medical product regulatory submission based on a non-randomized study. It should also be noted that propensity score methods may not eliminate all bias resulting from imbalance in the observed covariates, due to the intrinsic limitation of propensity score modeling.

Braitman and Rosenbaum^[3] state that the propensity score methods work better when there are a large number of subjects in each treatment group and when there are many covariates measured. In a regulatory setting, it may be inappropriate to conduct propensity score analysis when sample size is small because small sample size could result in some propensity score subclasses, such as propensity score quintiles, containing subjects from only the treated group or only the control group.^[18] Also, although it is expected that all observed covariates could be balanced between the treated and control groups through propensity scores, in a small non-randomized study, substantial imbalance of some covariates might be unavoidable despite the use of a sensible propensity score model. On the other hand, it is essential to collect a rich set of clinically relevant baseline covariates that are potentially related to both treatment assignment and clinical outcomes, in order to minimize residual bias.^[17] These covariates should be well measured in the study and used in the study design and outcome analysis.

PROPENSITY SCORE APPLICATIONS

Regarding the application of the propensity score methodology, a notable distinction between the exploratory work of general research and the confirmatory study in the regulatory setting is the necessity of prespecification of study objectives and outcome-free study design in the latter.^[18–21] Rubin^[13–15] points out that the propensity score methodology can be utilized to design an observational study without any access to any outcome data, thereby ensuring the objectivity of the design. Here, the study design refers to the process of propensity score estimation and covariate balance assessment, as well as the development of statistical analysis plan (SAP). These should be carried out objectively, that is, in an outcome-free manner. The study design also encompasses identification of control group and baseline covariate to be collected as well as sample size and power considerations.

Objective Study Design

In the regulatory setting, the prospective design of a non-randomized confirmatory study or observational postmarket study based on propensity score is particularly essential for providing objective evidence of safety and effectiveness.^[19–22] The prospective design using propensity scores can be carried out in two stages as proposed by Yue, Lu, and Xu.^[22] The first design stage is completed before the initiation of the investigational study. One main task at the beginning of this stage is to identify an independent statistician. This statistician needs to be blinded to any outcome data throughout the entire design stage. Some masking mechanism, such as a firewall, should be planned in this stage to control access of outcome data.

The planning of the initial sample size should also be done during the first stage. The second design stage should be initiated as soon as subject enrollment is concluded and baseline covariates data are collected, cleaned, and locked.^[22,23] The independent statistician identified in the first design stage should perform the task of estimating the propensity scores, matching subjects based on the propensity scores, and assessing the covariate balance. This may involve an iterative process until the balance is reached in the covariate distributions. The SAP should be finalized at this stage. Note that in the study design phase, only the treatment assignment and baseline covariate data are needed. The outcome data are not required nor should they be accessed.

Covariate Balance Diagnostics

Covariate balance assessment is crucial in the iterative process of propensity score modeling. In mimicking randomized clinical trials, propensity score methods are used in observational studies to achieve the distributional balance of baseline covariates between the treated and control groups. However, it is by no means guaranteed that balance is achieved, and so balance should be checked. Some graphical methods (such as side-by-side boxplots and LOVE plots)^[24] and numerical diagnostics^[2–17] are available, none of which is sufficient on its own.

One graphical method compares the distributions of the estimated propensity scores between the treated and the control groups to see whether there is sufficient number of subjects in the two groups that are similar enough to make treatment comparison on outcomes (common support). Without sufficient overlap, one may have no choice but to conduct the study only on a subset of the patients. However, in so doing, the generalizability of the study may be limited. In the premarket setting in particular, exclusion of patients treated with the investigational medical product could lead to the dangerous consequence of possibly changing its intended use by changing the patient population and such post hoc change could be problematic. On the other hand, good overlap in the propensity score distributions does not guarantee covariate balance. Therefore, it is necessary to demonstrate that the distributions of the baseline covariates are similar between the treatment groups, after the propensity score adjustment. With propensity score matching, the covariate balance assessment should be made on the matched samples. When propensity score stratification is used, the covariates should be balanced within each stratum.

One of the most commonly used numerical balance diagnostics is the “standardized difference in means,” which is the absolute value of difference in means of each covariate, divided by the pooled standard deviation.^[16–25] It is pointed out that statistical significance testing should not be used as a measure of covariate balance,^[26–27] and the

c-statistic of the propensity score model does not provide an appropriate assessment of covariate balance.^[26–28]

Covariate Selection and Identification

There is no consensus in the literature as to which baseline covariates to include in the propensity model. Four possible sets of baseline covariates are considered:^[25] all observed baseline covariates, all baseline covariates that are associated with treatment assignment, all covariates that affect the outcome (i.e., the potential confounders), and all covariates that affect both treatment assignment and the outcome (i.e., the true confounders). To satisfy the assumption of ignorable treatment assignment in the propensity score methodology (i.e., no unobserved difference between the two treatment groups conditional on the observed covariates), it is important to include all covariates known to be related to both treatment assignment and outcomes.^[29,30] In practice, it may be difficult to make a judgment on whether a covariate is a confounding variable. Therefore, it is better to include as many variables as possible that are collected in a study, particularly in a premarket confirmatory study, as failure to include a key confounding variable in the propensity score model could lead to a substantially biased estimate of treatment effect on outcomes.^[23]

The covariates to be collected and included in the propensity score modeling should be prospectively identified. Identification of such covariates should be a thoughtful process based on scientific reasoning and up-to-date clinical research. This process needs to be outcome-free to avoid potential bias and to ensure the validity of study conclusion.^[13,22]

It should be emphasized that the propensity score model should only include covariates that are observed at baseline and not posttreatment covariates that may be influenced or modified by the treatment.^[25]

Control Group Selection

It is crucial to select the control group from a relatively comparable patient population to begin with, since propensity score methods may not work (in fact, no statistical method would work) when there is serious imbalance in baseline covariates between the two treatment groups.^[18,22] However, it is sometimes impossible to predict in advance whether the patient population with an investigational medical product is comparable to that with a control, which is a risk for all non-randomized studies.

Sample Size Estimation and Power Consideration

In general, the more comparable the baseline covariates between treatment and control groups are, the smaller the sample size that is required to achieve desired power. When

using propensity score methodology to design a study, the degree of non-comparability of two treatment groups and the propensity score adjustment should be taken into account in sample size estimation.^[22] However, it is sometimes difficult to predict in advance and hence hard to make assumptions on treatment group comparability.

Sample size determination may depend on the particular subject matching approach to be used. For example, stratification and 1:1 matching may lead to different sample sizes. It may also depend on analysis methods for outcomes. Therefore, it is important to plan the sample size under various design/analysis scenarios.^[22]

Missing Data in Covariates

It is common for a large number of baseline covariates to be measured and collected, as in cardiovascular device studies. This could result in a large proportion of patients with at least one covariate value missing. Without any action on the missing covariate values, these subjects could be automatically excluded from propensity score modeling and then from treatment comparison with respect to clinical outcome, leading to questionable study results.

Missing data in covariates can be dealt with by using the familiar method of multiple imputation or some adaptations thereof.^[9] After missing data have been imputed, propensity score models can be built, one for each of the m completed data sets. One approach to estimating the treatment effect is to obtain a single propensity score for each patient as the average of the m propensity scores from the m models and then use this average propensity score to generate a single estimate of the treatment effect. Another approach is to use the m propensity score models to generate m treatment effect estimates and then combine those m estimates. Mitra and Reiter^[31] compared those two approaches via simulation studies and suggested that the first approach has greater potential to produce substantial bias reductions.

Outcome Analysis

Once the propensity score model is finalized, matching or stratification is implemented, and covariate balance is found to be adequate, outcome data can be unblinded and outcome analysis can start. If propensity score matching is used, there is debate about whether outcome analysis needs to take into account the matched nature of the data.^[17,25] If propensity score stratification is used, then treatment effect is estimated as a weighted average across strata. One weighting scheme produces an estimate of the average treatment effect, which is the average effect of moving an entire population from control to treated. Another weighting scheme produces an estimate of the average treatment effect on the treated (ATT), which is the average effect of treatment on those subjects who ultimately received the treatment.^[25] When

choosing a weighting scheme, it should be kept in mind that the estimand needs to be clinically meaningful.

CONCLUSION

Propensity score methodology expands techniques that use just one confounding covariate, allows simultaneous adjustment for many observed covariates, and thus reduces bias in treatment comparisons. It could be used to approximate randomized clinical trials and transparently design and analyze observational studies. One unique feature of propensity score methods, be it propensity score matching, stratification, or IPTW, is the ability to separate study design and outcome analysis, which is an essential requirement in clinical studies submitted for regulatory review. The methodology has been used in premarket comparative observational (non-randomized) medical device studies, using a concurrent (but non-randomized) control, a historical control formed from patients with existing data collected from earlier studies of a previously approved device, or a control group extracted from a well-designed and executed national or international patient registry database. It has also been utilized in drug safety comparative observational studies, using electronic medical record databases or administrative health-care databases to estimate treatment effects of intervention.^[21] We believe that the application of propensity score methodology in clinical studies will continue to grow in the future.

Abstract

A proportion of treatment effect is defined as a putative surrogate endpoint as a measure of ascertaining the magnitude of the causal pathway accounted for by the treatment effect on the surrogate biomarker. This entry focuses on the impact of the proportion treatment effect has on determining surrogate endpoint biomarkers.

INTRODUCTION

A surrogate endpoint of a clinical trial is a surrogate biomarker intended to supplant a clinical endpoint, characteristic, or variable that directly reflects how a patient feels or functions, or how long a patient survives.^[1] Examples of “true” clinical endpoints are death, stroke, myocardial infarction, loss of vision, progression to AIDS, and other events that cause a substantial reduction in quality of life. Since true clinical endpoints do not occur often, clinical trials that use them as primary endpoints are usually large and may take years to complete. During the development of a pharmaceutical product, it is often unfeasible or impractical to conduct such trials, and surrogate endpoints have to be considered to save time and cost. However, a surrogate biomarker has to be validated before it can be accepted as a surrogate endpoint.

Surrogate endpoints have been of clinical interest for decades, but it was not until Prentice published a seminal paper in 1989 that formal statistical validation started.^[2] Prentice defined a surrogate endpoint as “a response variable for which a test of the null hypothesis of no relationship to the treatment groups under comparison is also a valid test of the corresponding null hypothesis based on the true endpoint.” This definition is stringent and impracticable. To overcome the problem, Freedman, Graubard, and Schatzkin^[3] proposed the so-called “proportion of treatment effect” (PTE), explained by a putative surrogate endpoint as a measure of ascertaining the magnitude of the causal pathway accounted for by the treatment effect on the surrogate biomarker. The proposal was made in the context of logistic regression models, and was subsequently extended to Cox regression models by Lin, Fleming, and De Gruttola,^[4] which is arguably more pertinent to surrogate validation and will be used as the primary platform for presentation.

The conventional procedure for a PTE estimation fits data into two working models separately to estimate the treatment effects before and after adjustment for the covariate corresponding to the surrogate biomarker of interest. The construction of confidence intervals for the PTE under the conventional procedure lacks support by standard statistical software such as SAS, and could be very computationally demanding even if the support is available in the future. To overcome this problem, Chen, Wang, and Snapinn^[5] proposed a procedure to simplify the computation. Under the new procedure, the treatment effects before and after adjustment for the covariate are simultaneously estimated from a single model. More important than saving computational effort, the idea of using a single model can also be effectively applied to multiple-covariate analysis for the decomposition of overall treatment effect and for the comparison of PTE among several surrogate biomarkers.

STATISTICAL CONCEPT AND METHODS

PTE Estimation Based on Two Separate Models

Consider survival data generated from a clinical trial with repeated measurements of a surrogate biomarker over time for each patient. Suppose there are two treatment groups (new treatment and placebo, say), and R is the treatment indicator, which takes value 1 for the new treatment and 0 for placebo. Denote by X the surrogate biomarker, and by $X(t)$ the measurement of X at time t . The PTE calculation starts with the following two Cox regression models:

$$\lambda_1(t | R) = \lambda_{10}(t) \exp\{\alpha_1 R\} \quad (1)$$

$$\lambda_2(t | R, X) = \lambda_{20}(t) \exp\{\alpha_2 R + \beta X(t)\} \quad (2)$$

where $\lambda_{10}(t)$ and $\lambda_{20}(t)$ are unspecified baseline hazard functions, and α_1 , α_2 , and β are unknown regression coefficients.

The instantaneous event rate is assumed to be proportional to $\exp\{\alpha_1 R\}$ under the first model, and is assumed to be proportional to $\exp\{\alpha_2 R + \beta X(t)\}$ under the second model. Note that α_1 estimates the overall treatment effect before any adjustment and α_2 estimates the treatment effect after the adjustment for the biomarker effect; the PTE explained by the biomarker is naturally defined to be $1 - \alpha_2/\alpha_1$. This definition is very intuitive and appealing to medical researchers.

After data are fit to the two models separately and the estimates of (α_1, α_2) are available, the estimation of PTE is straightforward. The PTE estimates the magnitude of the surrogate effect. As to what extent of surrogacy PTE suggests, it is arguably more important to construct the associated confidence intervals than fixating upon the point estimate. For example, a 95% confidence interval for PTE of (0.40, 1.05) suggests that the surrogate biomarker under consideration explains at least 40% of the treatment effect. To construct the confidence interval, we need the covariance matrix of the estimates for (α_1, α_2) . However, because the two models in general do not hold simultaneously, there is a lot of difficulty in the estimation of the covariance matrix. To address the issue, Lin, Fleming, and De Gruttola^[4] proposed a sandwich type covariance matrix to account for model misspecifications. But it is not supported by standard statistical software such as SAS, and, due to its jackknife nature, could be very computationally demanding even if the support is available in the future.

PTE Estimation Based on a Single Model

Chen, Wang, and Snapinn^[5] proposed to estimate PTE solely based on a single model so that the statistical property of the PTE estimate could be easily characterized. The idea is to separate information between the treatment indicator and the surrogate biomarker, and recover the unadjusted treatment effect directly from the second model, which is assumed to be the complete model. Rewrite the model as

$$\lambda_2(t | R, X) = \lambda_{20}(t) \exp\{(\alpha_2 + c\beta)R + \beta(X(t) - cR)\} \quad (3)$$

where c is a tuning parameter to retain the unadjusted treatment effect in $\alpha_2 + c\beta$, or in other words, to make the adjusted surrogate biomarker $X(t) - cR$ balanced between the two treatment groups.

Let $(\hat{\alpha}_2, \hat{\beta})$ be the maximum partial likelihood estimates of (α_2, β) from fitting data to the complete model. They asymptotically follow a multivariate normal distribution,^[6] with estimated mean of $(\hat{\alpha}_2, \hat{\beta})$ and estimated covariance

matrix $\begin{pmatrix} \hat{\sigma}_R^2 & \hat{\rho}\hat{\sigma}_R\hat{\sigma}_X \\ \hat{\rho}\hat{\sigma}_R\hat{\sigma}_X & \hat{\sigma}_X^2 \end{pmatrix}$. An estimate of c is obtained from

$\text{cov}(\hat{\alpha}_2 + c\hat{\beta}, \hat{\beta}) = 0$ and is given by $\hat{c} = -\hat{\rho}\hat{\sigma}_R/\hat{\sigma}_X$. This is equivalent to using the estimated information matrix as the basis to measure dependence as suggested by Zografos^[7] for information separation. Because $\hat{\alpha}_2 + \hat{c}\hat{\beta}$ and $\hat{\beta}$ are uncorrelated, the information in R with respect to clinical outcomes would be largely separated from that in $X(t) - \hat{c}R$ (the following section provides more details on information separation). Therefore, the unadjusted treatment effect is estimated to be $\hat{\alpha}_2 + \hat{c}\hat{\beta}$, and the corresponding estimate of the PTE is

$$\hat{P} = 1 - \frac{\hat{\alpha}_2}{\hat{\alpha}_2 + \hat{c}\hat{\beta}} = \frac{\hat{c}\hat{\beta}}{\hat{\alpha}_2 + \hat{c}\hat{\beta}} \quad (4)$$

Given $\hat{c}$, $\hat{P}$ is a ratio of two random variables with independent asymptotic normal distributions. From the estimated covariance matrix of $(\hat{\alpha}_2, \hat{\beta})$, the confidence interval of PTE can be easily constructed by using the delta-method, Fieller's method,^[8] or parametric bootstrap.^[9]

Proportion of treatment effect estimates based on the single-model approach and the two-model approach are not expected to be the same in general. This is because when $\beta \neq 0$, $\alpha_2 + c\beta$ is not equal to α_1 even when $X(t) - cR$ is independent of R .^[10] However, it is of interest to make a comparison. To illustrate, we draw an analogy to a problem in regular linear regressions. Let $Y = \alpha_2 R + \beta X + \varepsilon$ be the true model with ε independent of (R, X) . Suppose that R and X are standardized variables, both with mean 0 and variance 1, and $\text{corr}\{R, X\} = \theta$. Let $Y = \alpha_1 R + \omega$ be the reduced model with covariate X omitted. Then the least squares estimate of α_1 from the reduced model would converge to $\text{corr}\{R, Y\} = \alpha_2 + \theta\beta$, exactly the same as the unadjusted treatment effect derived from the true model using the information separation procedure as just discussed. Therefore, the PTE estimates converge to the same quantity under the two approaches.

The idea of using a single model for PTE estimation can be easily extended to multivariate analysis. Consider a Cox regression model with m time-varying covariates,

$$\lambda(t | R, X) = \lambda_0(t) \exp\left\{\alpha R + \sum_{k=1}^m \beta_k X_k(t)\right\} \quad (5)$$

where $X_k(t)$ is the measurement of the surrogate biomarker X_k at time t , $k = 1, \dots, m$. Similar to the single covariate case, the above model can be rewritten as

$$\lambda(t | R, X) = \lambda_0(t) \exp\left\{\left(\alpha + \sum_{k=1}^m c_k \beta_k\right)R + \sum_{k=1}^m \beta_k (X_k(t) - c_k R)\right\} \quad (6)$$

where $(c_1, \dots, c_m)$ are tuning parameters to retain the unadjusted treatment effect in $\alpha + \sum_{k=1}^m c_k \beta_k$, of which $c_k \beta_k$ is the

contribution from $X_k(t)$, and α is the contribution from sources other than $\{X_1(t), \dots, X_m(t)\}$. After data are fit to the Cox regression model^[5] and the maximum partial likelihood estimates of $(\alpha, \beta_1, \dots, \beta_m)$, denoted by $(\hat{\alpha}, \hat{\beta}_1, \dots, \hat{\beta}_m)$, together with an estimate of the covariance matrix are obtained, the tuning parameters are estimated from the following system of equations;

$$\text{Cov}\left(\hat{\alpha} + \sum_{k=1}^m c_k \hat{\beta}_k, \hat{\beta}_j\right) = 0 \quad \text{for } j = 1, \dots, m \quad (7)$$

Once the estimates of $(c_1, \dots, c_m)$, denoted by $(\hat{c}_1, \dots, \hat{c}_m)$, are available, the PTE by X_j is

$$\hat{c}_j \hat{\beta}_j / \left(\hat{\alpha} + \sum_{k=1}^m \hat{c}_k \hat{\beta}_k \right).$$

It is clear from the above discussion that PTE, by definition, can also take negative values or values >1 . This is not surprising, because overall treatment effect can be viewed as the net effect from all sources, which could take values of possibly opposite signs. Consequently a PTE estimate is just the estimate of a ratio that might take any value. When it is negative, it means the new treatment has a detrimental effect through the biomarker compared to the placebo; when it is >1 , it means that the new treatment has some other effects in the opposite direction to that reflected in the biomarker under evaluation.

Information Separation

The concept of information separation used in the single-model approach apparently has wide applications unconfined to Cox regression models. It can be directly adapted to any statistical models capable of providing point estimates of parameters of interest and corresponding estimate of the covariance matrix. We use linear regression models to provide a more detailed explanation behind the concept.

Let R be an indicator of treatment group that takes value 1 or -1 , each with probability $1/2$, and X be an m -dimensional column vector of standardized covariates, each with mean 0 and variance 1. Denote by F the covariance matrix of X . Assume that $E\{X|R\} = AR$. Suppose that the response variable Y is associated with (R, X) in the following linear regression model:

$$Y = \alpha R + \beta' X + \varepsilon \quad (8)$$

where ε is a standardized random error independent of (R, X) . Observe that, by definition, $\text{cov}(R, X) = A$. The adjusted treatment difference between $R = 1$ and $R = -1$ is naturally 2α as per the definition of R , and the unadjusted treatment difference is

$$E\{Y | R = 1\} - E\{Y | R = -1\} = 2(\alpha + \beta' A) \quad (9)$$

Denote by $(\hat{\alpha}, \hat{\beta}')$ the least squares estimator of (α, β') , and by M the covariance matrix of $(\hat{\alpha}, \hat{\beta}')$. Based on standard linear regression theory,

$$M = \begin{pmatrix} \text{var } \hat{\alpha} & \text{cov}(\hat{\alpha}, \hat{\beta}') \\ \text{cov } \hat{\beta} & \text{cov}(\hat{\beta}, \hat{\beta}') \end{pmatrix} = \frac{1}{n} \begin{pmatrix} 1 & A' \\ A & F \end{pmatrix}^{-1} \quad (10)$$

where n is the sample size. Under the information separation procedure, model (8) is rewritten as

$$Y = (\alpha + \beta' c) R + \beta' (X - cR) + \varepsilon \quad (11)$$

where c again is a vector of tuning parameters solved from $\text{cov}(\alpha + \beta' c, \hat{\beta}) = 0$. By applying standard matrix theory^[11] to (10),

$$\begin{aligned} c &= -\text{cov}(\hat{\beta}', \hat{\beta})^{-1} \text{cov}(\hat{\alpha}, \hat{\beta}) \\ &= -\text{cov}(\hat{\beta}', \hat{\beta})^{-1} \left(-\text{cov}(\hat{\beta}', \hat{\beta})^{-1} A \right) = A \end{aligned} \quad (12)$$

Therefore, the unadjusted treatment effect under the information separation procedure is the same as in (9), and so are the corresponding PTEs. However, the natural approach in (9) involves the calculation of $\text{cov}(R, X)$, which could be cumbersome when X is a time-varying covariate. The information separation procedure is apparently more computationally flexible, especially in complex or non-linear models. Besides, unlike the information separation approach, the natural approach does not take advantage of the optimality property inherent in an information matrix.

CONCLUSIONS

The road to the supreme status of surrogacy has always been bumpy. Many surrogate biomarkers have been investigated in the past, but only a few have passed scientific scrutiny and are now well accepted as surrogate endpoints. In cardiovascular diseases, systolic blood pressure and low-density lipoprotein (LDL or bad cholesterol) are among a handful of commonly accepted surrogate endpoints for clinically important cardiovascular events after a long search. Other examples include intraocular pressure for preservation of vision and HIV RNA reductions for AIDS progression-free survival. A new drug can now be approved solely based on reduction of systolic blood pressure or LDL. But, it does not necessarily mean that the drug is always safe to use or marketing claims regarding the ultimate endpoint are allowed. For example, since it caused fatal rhabdomyolysis, cerivastatin (a cholesterol-lowering drug) was withdrawn from the market in August 2001 after years in use. Examples of weakness and limitation of surrogate endpoints can also be found in Ref. [12].

As was also pointed out in Ref. [12] one reason why many surrogate endpoints need further confirmation is that there might be multiple pathways of intervention. While current statistical methods mainly (for exceptions, see e.g., Ref. [13]) aim at testing whether a surrogate biomarker qualifies to be a surrogate endpoint one at a time, the single-model approach has the advantage of simultaneously evaluating multiple surrogate biomarkers and helping identify multiple causal pathways. The framework of using a single model for PTE analysis or surrogacy validation makes relevant statistical problems very tractable, and a spectrum of research work is warranted. A similar idea of using the single-model approach can also be found in Ref. [14].

Just like Prentice's definition of surrogate endpoint, though intuitive and appealing the PTE idea is not immune to criticism. Proportion of treatment effect estimation could be very sensitive to the handling of errors in surrogate biomarker measurements^[15] and other modelling aspects. Researchers have also found that definite conclusions can seldom be drawn based on PTE estimation, as it usually has a wide confidence interval. But for the confidence interval to be narrow, clinical trials have to be large and the study duration has to be long, which is exactly what researchers try to avoid in the first place. Despite these caveats, interesting clinical conclusions such as the impact of serum uric acid on cardiovascular endpoint are routinely drawn based on PTE analysis.^[16] To partly overcome the dilemma with PTE, Buyse et al.^[17] and Molenberghs et al.^[18] proposed to validate surrogacy by combining data from similar trials, and to use two new quantities to replace PTE as measures of surrogacy. An alternative definition of PTE can also be found in Ref. [19].

Statistical methods such as PTE analysis provide powerful tools for surrogacy validation. However, they have a fundamental limitation. They can help identify associations or lack thereof, but statisticians need input from medical science to put forth mechanisms for possible explanation of whether or not the identified relationship is independent or causal. Statisticians do not work alone in surrogacy validation, just as in any applied statistical field. As new surrogate biomarkers are routinely discovered in bioscience and technology, statistical methods have to be improved to meet the growing need. This could continue to make the related statistical field one of the hottest in statistics for years to come.

Abstract

The proportional hazards regression model has become, by a wide margin, the most used regression model for analyzing time-to-event data because of its flexibility and availability in software packages. This entry breaks down each part of this model in detailed terms.

Keywords: Proportional hazards; Regression model; Residuals.

INTRODUCTION

An objective of many medical studies is the prognostic assessment of time to an event, denoted T , such as the remission of symptoms, the progression of a disease, or the onset of death. Clinical studies can be designed to obtain information concerning possible prognostic factors, and a physician can usually decide as to which factors may be relevant. However, a meaningful summary of the data to reveal the underlying relationship between the time to the occurrence of the event and the various predictors can only be achieved through a comprehensive statistical analysis.

Time to an event is often called a *failure time*, *survival time*, or *event time* in the literature. It is the interval between a clearly defined time origin and the occurrence of an event of interest. The time origin need not be at the same calendar time for each individual. An important consideration in the choice of a time origin is that, subject to any known differences on individual characteristics, all individuals should be as comparable as possible at their time origin. Most *randomized clinical trials*, for example, have staggered entry; the event time of a subject is usually measured from the day the subject is randomized to receive one of the treatment protocols. It is customary to refer to the event of interest as *failure* in clinical trials because it is usually some negative individual experience such as death.

A mechanism that can lead to an incomplete observation of an event time is *censoring*. Broadly speaking, a censored observation arises when the exact event time is unknown, but can only be determined to lie within a certain interval. The most commonly encountered form of a censored observation is one in which the observation on a patient begins at the randomization, and ceases before the event of interest is realized, when the patient is lost to follow-up. Such observations are said to be *right-censored*

because the incomplete nature of the observation occurs in the right tail of the time axis. For example, in a study designed to evaluate survival after a confirmed diagnosis of HIV, some subjects may die from AIDS or AIDS-related causes before the end of the study, yielding exact survival times; others may withdraw before the end of the study; still others may be alive at the end of the study. The last two kinds of observations are right-censored observations because the survival status is only known until the last contact.

OVERVIEW

Other censoring mechanisms that can occur in practice include *left censoring*, when all that is known is that the event has already occurred before a certain time, and *interval censoring*, when the only information available is that the event occurs within some interval.

Whatever the cause of censoring, a key assumption is that the censoring is *noninformative* about the event of interest, that is, the cause of censoring is unrelated to the impending event. A systematic withdrawal of high-risk or low-risk patients from a study is an example of informative censoring, which may result in inaccurate statistical inference about the survival experience. Kalbfleisch and Prentice^[1] (Section 5.2) provide further discussion of noninformative censoring.

Censoring is an inherent feature in time-to-event data, which creates special problems in the analysis of such data. In particular, it renders the usual linear regression analysis inappropriate because the response, the event time, is incompletely determined for some observations. Regression models proposed for prognostic modeling of time-to-event data generally involve assumptions on the

hazard function, which describes the way in which the instantaneous risk of an individual experiencing an event changes over time. One such model is the *proportional hazards regression model* introduced by Cox.^[2] It has become, by a wide margin, the most used regression model for analyzing time-to-event data because of its flexibility and availability in software packages.

THE MODEL

Let $\mathbf{x} = (x_1, x_2, \dots, x_p)^T$ be p measured covariates (or predictor variables) on a given individual, where the symbol T denotes transpose. These can be patient characteristics, such as gender or race, or these can be factors of particular interest, such as the treatment received during a drug trial. The coding of categorical variables follows the usual rules in ordinary regression analysis. It is assumed, for now, that the values of the covariates for any given individual remain constant over time. Such covariates are called *fixed-time* or *time-independent* covariates.

The *Cox model*, in its simplest form, postulates that the hazard function at time t for an individual with covariate values $\mathbf{x}$ is:

$$\begin{aligned} \lambda(t | \mathbf{x}) &= \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} pr\{t \leq T \leq t + \Delta t | T \geq t, \mathbf{x}\} \\ &= \lambda_0(t) \exp(\beta^T \mathbf{x}) \end{aligned} \quad (1)$$

where $\lambda_0(t)$ is an arbitrary, non-negative function of time; $\beta = (\beta_1, \beta_2, \dots, \beta_p)^T$ is a vector of unknown regression coefficients; and $\beta^T \mathbf{x} = \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_p x_p$. The function $\lambda_0(t)$ characterizes the dependence of the hazard function on time. The subscript 0 on $\lambda_0(t)$ reflects that it is the hazard function for an individual with all covariate values equal to zero; for this reason, $\lambda_0(t)$ is referred to as the *baseline hazard function*. The function $\exp(\beta^T \mathbf{x})$ characterizes how the hazard function changes as a function of covariate values. Notice that there is no intercept parameter (or constant term) in $\beta^T \mathbf{x}$, for it is subsumed in $\lambda_0(t)$. In prognostic modeling, attention is usually focused on inference about specific regression coefficients or on $\beta^T \mathbf{x}$ (which is sometimes known as the *risk score* or *prognostic index* for an individual with covariate values $\mathbf{x}$), while $\lambda_0(t)$ is often considered a nuisance parameter.

Besides the hazard function, a function of central interest in the analysis of time-to-event data is the *survival function*, which gives the probability that an individual has yet to experience the event of interest at a specified time. Under the Cox model, the survival function at time t for an individual with covariate values $\mathbf{x}$ has the form:

$$S(t | \mathbf{x}) = [S_0(t)]^{\exp(\beta^T \mathbf{x})} \quad (2)$$

where $S_0(t)$ is the *baseline survival function*, that is, the survival function for an individual with all covariate values

equal to zero. The baseline survival function is related to the baseline hazard function through the equation:

$$S_0(t) = \exp[-\Lambda_0(t)] \quad (3)$$

where $\Lambda_0(t) = \int_0^t \lambda_0(u) du$ is called the *cumulative* (or *integrated*) *baseline hazard function*.

The Cox model can be derived as a special case of a class of linear transformation models (Ref. [3], Section 4.7) given by:

$$g(T) = -\beta^T \mathbf{x} + \varepsilon \quad (4)$$

where $g(\cdot)$ is an unknown monotone transformation and ε is a random variable with completely specified distribution. The Cox model results when $g(\cdot) = \log \Lambda_0(\cdot)$ and ε has a unit extreme value distribution.

The Cox model is a *semiparametric model* in the sense that the covariate effect is modeled parametrically, while no assumption is made regarding the functional form of the time effect. As we shall see later, that $\lambda_0(t)$ is left completely unspecified does not sacrifice the ability to obtain a reasonably good estimate of β . The log-linear form $\exp(\beta^T \mathbf{x})$ assumed for the covariate effect can be replaced by any known function of $\mathbf{x}$ and β that is nonnegative, such as a *cubic spline*.^[4] A variety of probability models can be used to specify $\lambda_0(t)$ to yield fully parametric proportional hazards regression models. For example, a *Weibull distribution* with scale parameter α and a shape parameter γ is flexible enough to accommodate increasing ($\gamma > 1$), decreasing ($\gamma < 1$), or constant ($\gamma = 1$) time effect: $\lambda_0(t) = \alpha \gamma t^{\gamma-1}$. The utility of the Cox model stems from the fact that in most applications, the form of $\lambda_0(t)$ is either unknown or complex, and if a parametric model is chosen incorrectly, it could lead to estimators of the wrong quantity. The Cox model is a *robust* model, in the sense that if the correct parametric model is, say, Weibull, then the use of the Cox model typically will give results comparable to those obtained using a Weibull model.

In the Cox model, as expressed in Eq. 1, the regression coefficient β_k (where $k = 1, 2, \dots$, or p) describes the change in the hazard function on a logarithmic scale for a change in the corresponding covariate x_k of one unit, while all other covariates are kept fixed. We note that the ratio of hazards for an individual with covariate values $\mathbf{x}$ compared with an individual with covariate values $\mathbf{z}$ is:

$$\frac{\lambda(t | \mathbf{x})}{\lambda(t | \mathbf{z})} = \frac{\lambda_0(t) \exp(\beta^T \mathbf{x})}{\lambda_0(t) \exp(\beta^T \mathbf{z})} = \exp \left\{ \sum_{k=1}^p \beta_k (x_k - z_k) \right\} \quad (5)$$

which is constant through time. Suppose x_k is a dichotomous covariate such as smoking status, which is often coded so that smokers correspond to a value of 1 and non-smokers correspond to a value of 0. If the value of the coefficient is $\beta_k = \log 2$, then the interpretation is that at any

given point in time, smokers are twice as likely to experience the event of interest (such as death) compared to nonsmokers, all else being equal. Part of the appeal of the Cox model lies in such interpretations of the hazard ratio as the *relative risk* of exposure to a potential hazard. The evaluation of relative risk allows, for example, an insurance company to determine if smokers should pay a higher premium than nonsmokers.

Although the primary application of the Cox model is the consideration of relative risk, the absolute (or overall) risk is of interest when the purpose is prediction. For example, the risk of death before a certain age is essential for calculating the actual premiums of smokers (or nonsmokers). The hazard function $\lambda(t|x)$ is useful for characterizing the absolute risk, for it allows us to determine the probability that the event of interest will occur in the next instant, given that the event has not occurred. A related quantity is the *cumulative hazard function*: $\Lambda(t|x) = \int_0^t \lambda(u|x) du$ which describes the accumulated risk up until time t .

ESTIMATION

A major contribution of the article by Cox^[2] is the enunciation of a clever method for estimating the regression coefficients separately from the arbitrary baseline hazard function. This method is appropriate for both uncensored and right-censored data. Based on a sample of n individuals, the observed data consist of the triplets (t_i, δ_i, x_i) , $i = 1, 2, \dots, n$, where the subscript i denotes individual i ; t_i is the “observation” time, which is either the event time or the censoring time, depending on whether the event of interest had occurred by time t_i ; δ_i is the event indicator, that is, $\delta_i = 1$ if the event of interest had occurred (so that t_i is the event time) and $\delta_i = 0$ otherwise (so that t_i is the censoring time); and $x_i = (x_{i1}, x_{i2}, \dots, x_{ip})^T$ is the covariate values associated with the individual.

ESTIMATION OF REGRESSION COEFFICIENTS FOR DISTINCT EVENT TIME DATA

If there are no ties between the event times, the estimation of β is based on the *partial likelihood* introduced by Cox,^[2] which has the form:

$$L(\beta) = \prod_{i=1}^n \left[\frac{\exp(\beta^T x_i)}{\sum_{k \in R(t_i)} \exp(\beta^T x_k)} \right]^{\delta_i} \quad (6)$$

where $R(t_i) = \{k : t_k \geq t_i\}$, termed the *risk set* at time t_i , is the set of individuals at risk of experiencing the event of interest an instant before time t_i . Here the summation in the denominator is over all individuals whose observation

times are at least t_i . Note that the ordering of the observation times, rather than the actual observation times, is used in the calculation of $L(\beta)$. This renders the estimation procedure more robust to outliers in the observation times, as only the rankings of the times are used.

To understand the partial likelihood, it is useful to note that individuals whose event times were censored contribute factors of 1 (which contains no information about β) to the partial likelihood. The product in Eq. 6 is therefore effectively over all individuals who experienced the event of interest. For each of these individuals, the contribution to the partial likelihood represents the conditional probability of the individual experiencing the event given that there was an event at that time: among those individuals still at risk:

$$\begin{aligned} & \Pr\{\text{individual } i \text{ experiences the event at time } t_i | R(t_i) \\ & \quad \text{and an event at time } t_i\} \\ &= \frac{\Pr\{\text{individual } i \text{ experiences the event at time } t_i | R(t_i)\}}{\Pr\{\text{an event at time } t_i | R(t_i)\}} \quad (7) \\ &= \frac{\lambda_0(t_i) \exp(\beta^T x_i)}{\sum_{k \in R(t_i)} \lambda_0(t_i) \exp(\beta^T x_k)} \end{aligned}$$

Notice that $\lambda_0(t_i)$ cancels in Eq. 7, allowing inferences on β not involving the nuisance parameter.

The term “partial likelihood,” rather than (complete) likelihood, is used because the formula in Eq. 6 does not explicitly consider the probabilities for those individuals who were censored. Nevertheless, as discussed by Johansen,^[5] the Cox partial likelihood can be derived as a *profile likelihood* for β from the full likelihood. First, the full likelihood is set up as a function of both β and λ_0 :

$$\begin{aligned} L_F(\beta, \lambda_0) &= \prod_{i=1}^n [\lambda(t_i | x_i)]^{\delta_i} S(t_i | x_i) \\ &= \prod_{i=1}^n [\lambda_0(t_i) \times \exp(\beta^T x_i)]^{\delta_i} \exp[-\Lambda_0(t_i) \exp(\beta^T x_i)] \end{aligned}$$

We then maximize $L_F(\beta, \lambda_0)$ as a function of λ_0 only, using a discretization similar to the *Nelson-Aalen estimate* of the hazard function for data without covariates.^[6] Let $\hat{\lambda}_\beta$ denote the maximizer of $L_F(\beta, \lambda_0)$ for a given β . Note that $\hat{\lambda}_\beta(t) = 0$ except at observed event times. The profile likelihood is defined as the function: $pl(\beta) = \sup_{\lambda_0} L_F(\beta, \lambda_0) = L_F(\beta, \hat{\lambda}_\beta)$. The Cox partial likelihood is proportional to $pl(\beta)$.

The estimate for β is found by maximizing Eq. 6, or, equivalently, the logarithm of Eq. 6. This involves solving for $\beta_1, \beta_2, \dots, \beta_p$ in the set of p nonlinear equations:

$$\frac{\partial \log L(\beta)}{\partial \beta_j} = 0, \quad j = 1, 2, \dots, p \quad (8)$$

which can be done numerically by using the Newton-Raphson method of iteration (or some other iterative method). The solution to Eq. 8 is called the *maximum partial likelihood estimate* (MPLE), which we shall denote as $\hat{\beta} = (\hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_p)^T$. The estimator of the covariance matrix of $\hat{\beta}$ is obtained in the same manner as in most maximum likelihood estimation applications. Let $\mathbf{I}(\beta)$ denote the negative of the matrix of second-order partial derivatives of the partial likelihood function $L(\beta)$, that is, the entry in the j th row and k th column of $\mathbf{I}(\beta)$ is:

$$\frac{\partial^2 L(\beta)}{\partial \beta_k \partial \beta_j} \quad (9)$$

where $i = 1, 2, \dots, p$ and $j = 1, 2, \dots, p$. $\mathbf{I}(\beta)$ is known as the *observed information matrix*. The estimator of the covariance matrix of $\hat{\beta}$ is the inverse of the information matrix evaluated at $\hat{\beta}$, $\hat{Var}(\hat{\beta}) = [\mathbf{I}(\hat{\beta})]^{-1}$. For the j th estimated coefficient $\hat{\beta}_j$ (where $j = 1, 2, \dots, p$), the estimated standard error is given by the positive square root of the j th diagonal element in $\hat{Var}(\hat{\beta})$.

Algorithms for the estimation of β are available in many software packages. The procedure Phreg in SAS and the function coxpk in S-Plus, for example, provide the MPLE of β and its standard error.

ESTIMATION OF REGRESSION COEFFICIENTS IN THE PRESENCE OF TIES

The partial likelihood in Eq. 6 was developed under the assumption of continuous event times, which rules out the possibility of ties among the event times (ties among the censoring times are allowed). Modifications to the partial likelihood are therefore needed when the data contain tied event times. An estimation of β is otherwise carried out in the same manner as in the case of distinct event times.

Kalbfleisch and Prentice^[1] derived an exact expression for the partial likelihood for data containing tied event times. The basis for its construction is to assume that ties have been introduced into the data by the grouping of continuous times into intervals. This is a reasonable assumption because the recording of time is often rounded to the nearest unit of measurement. Let $t_{(1)} < t_{(2)} < \dots < t_{(m)}$ denote the distinct, ordered event times. Of course, $m \leq n$. Suppose that, of the n individuals in the sample, d_i individuals realized their events at $t_{(i)}$, where $i = 1, 2, \dots, k$ and $\sum_{i=1}^k d_i = n$; in other words, there are d_i ties at $t_{(i)}$. The tied values could have been observed in any one of the $d_i!$ orderings of their values. The exact partial likelihood function is obtained by modifying the denominator of Eq. 6 to include each of these possible orderings for each $t_{(i)}$. Both SAS and S-Plus include the option (discrete and exact, respectively) of using the exact partial likelihood. If the number of ties at any event time is large, the amount of computation time required for evaluating the exact partial likelihood can

be prohibitive, and approximations to the exact partial likelihood are often used instead.

Breslow^[7] considered each of the tied observations as distinct and derived an approximation to the exact partial likelihood function that is identical to Eq. 6. In other words, the partial likelihood function in Eq. 6 is applied without modification to data containing tied event times. If the number of ties at each event time is small relative to the size of the corresponding risk set, then Breslow's approximation works well; otherwise, it could produce "estimated β coefficients too close to 0 in absolute value"^[8] because of multiple counting of individuals who realized the event in the denominator of Eq. 6. An alternative approximation is because of Efron.^[9] Hertz-Picciotto and Rockhill^[10] presented a simulation study, which shows that the Efron approximation performed far better than the Breslow approximation, even with heavy ties and fairly small sample sizes.

To understand the difference between the two approximations, one may view the problem of ties in terms of population average effects in longitudinal data analysis. This has been studied by Zeger et al.^[11] who demonstrated that the population average model, when compared to subject-specific model, consistently underestimated the magnitude of the coefficients for the fixed effects in a linear logistic model. Hertz-Picciotto and Rockhill^[10] suggest that if tied data represent population averages, then the Breslow approximation could be considered an unadjusted population average model, in which the downward bias is attributed to the loss of information that results from the grouping of tied observations in the numerator of the likelihood. The Efron approximation adjusts the denominator downward to compensate for such loss of information.

The Breslow approximation is the default method in SAS. The Efron approximation is the default method in S-Plus and is implemented in SAS as the efron option.

ESTIMATION OF SURVIVAL FUNCTION

It may be of interest to estimate the survival function for an individual with a given set of covariate values, say x_0 . The expression for the survival function given in Eq. 2 suggests that once an estimate of the regression coefficients is available, all we need is an estimate of the baseline survival function. The Breslow^[7] estimate of $S_0(t)$ is derived through an estimate of $\Lambda_0(t)$, given by:

$$\hat{\Lambda}_0(t) = \sum_{t_i \leq t} \sum_{k \in R(t_i)} \frac{\delta_i}{\exp(\hat{\beta}^T x_k)} \quad (10)$$

Note that $\hat{\Lambda}_0(t)$ is a step function with jumps at the observed event times only; in other words, when graphed as a function of time, $\hat{\Lambda}_0(t)$ is flat between two consecutive event times. If there are no covariates, $\hat{\Lambda}_0(t)$ reduces

to the Nelson-Aalen estimate; in that case, all the exponential terms in the denominator of Eq. 10 are 1. The Breslow estimate of $S_0(t)$ is $\hat{S}_0^B(t) = \exp[-\hat{\Lambda}_0(t)]$, which is obtained using the expression for $S_0(t)$ shown in Eq. 3.

An alternative estimate of $S_0(t)$, because of Kalbfleisch and Prentice,^[12] is an extension of the *Kaplan-Meier estimate* to allow for covariates. In the particular case where the event times are distinct, the Kalbfleisch-Prentice estimate is given by:

$$\hat{S}_0^{KP}(t) = \prod_{i: t_i \leq t} \left[1 - \frac{\delta_i \exp(\hat{\beta}_i^T x_i)}{\sum_{k \in R(t_i)} \exp(\hat{\beta}_k^T x_k)} \right]^{\exp(\hat{\beta}_i^T x_i)} \quad (11)$$

Each term in the product can be regarded as an estimate of the probability that an individual survives through the interval defined by two consecutive observed event times.^[13] In the no-covariate case, $\hat{S}_0^{KP}(t)$ reduces to the Kaplan-Meier estimate. When there are tied event times, $\hat{S}_0^{KP}(t)$ is found numerically by solving a system of equations.

Making use of Eq. 2, the estimated survival function for an individual with covariate values x_0 is: $\hat{S}(t|x_0) = [\hat{S}_0(t)]^{\exp(\hat{\beta}^T x_0)}$ where $\hat{S}_0(t)$ is either $\hat{S}_0^B(t)$ or $\hat{S}_0^{KP}(t)$. The SAS procedure phreg uses $\hat{S}_0^{KP}(t)$ by default, and $\hat{S}_0^B(t)$ can be chosen with the method=ch option. S-Plus has both $\hat{S}_0^B(t)$ and $\hat{S}_0^{KP}(t)$ available in the function surv.fit, along with the variance estimates.

The variance of $\hat{S}(t|x_0)$ is complex (e.g., see Ref. [14]); in the no-covariate case, it equals that for the Kaplan-Meier estimate.

ASSESSMENT OF MODEL ADEQUACY

Central to the assessment of model adequacy in any setting is an appropriate definition of a residual. In the usual regression setup, a natural definition of the residual is the difference between the observed value of the response and that predicted by the fitted model. In the regression analysis of time-to-event data, however, the definition of the residual is not as clear-cut, due in part to the possibility of incompletely observed response, and in part to the hazard formulation. Several residuals have been proposed for examining the different aspects of the fit of the Cox model.

Schoenfeld Residuals

A key assumption of the Cox model is proportional hazards, that is, the hazard ratio of individuals with distinct covariate values is constant over time. The validity of this assumption is vital to the interpretation of the regression coefficients. *Schoenfeld residuals*^[15] are useful for assessing the proportional hazards assumption for each covariate as well as several covariates simultaneously. There is not a single value of the residual for each individual, but a set of

values—one for each covariate included in the fitted Cox model.

The Schoenfeld residual for the i th individual on the k th covariate is given by:

$$s_{ik} = \delta_i \{x_{ik} - \bar{x}_k(\hat{\beta}, t_i)\} \quad (12)$$

where $\hat{\beta}$ is the MPLE, and: $\bar{x}_k(\hat{\beta}, t_i) = \sum_{j \in R(t_i)} x_{jk} \exp(\hat{\beta}^T x_j) / \sum_{j \in R(t_i)} \exp(\hat{\beta}^T x_j)$ is a weighted average of the values of the k th covariate over those individuals still at risk at the event time t_i of the i th individual, with $\exp(\hat{\beta}^T x_j)$ as the weight assigned to the j th individual in the risk set. Note that if the event time of the i th individual is censored, then $s_{ik} = 0$ for all k .

Some authors call the Schoenfeld residual in Eq. 12 the *score residual*, because s_{ik} can be derived as the i th individual's contribution to the first derivative of the log partial likelihood function with respect to β_k :

$$\frac{\partial \log L(\beta)}{\partial \beta_k} = \sum_{i=1}^n \delta_i \{x_{ik} - \bar{x}_k(\beta, t_i)\} \quad (13)$$

That is, s_{ik} can be regarded as an estimate of the i th term in the above summation, obtained by substituting $\hat{\beta}$ for β . Because $\hat{\beta}$ is the solution to the equations obtained by setting Eq. 13 to zero, the Schoenfeld residuals must sum to zero. Furthermore, in large samples, the expected value of s_{ik} is zero and the residuals are uncorrelated with one another. For this reason, the Schoenfeld residuals, when plotted against the event times for each covariate in the fitted model, should scatter in a nonsystematic way about the horizontal axis.

Grambsch and Therneau^[16] suggest that scaling the Schoenfeld residuals by an estimator of its variance yields a residual with greater diagnostic power than the unscaled residuals. Most software packages compute an approximate scaled Schoenfeld residuals, obtained by multiplying $m\hat{Var}(\hat{\beta})$ to the Schoenfeld residuals, where m is the number of uncensored event times.

Numerous tests of the proportional hazards assumption have been proposed. Grambsch and Therneau^[16] showed that most of these are essentially tests for zero slopes in a generalized linear regression of scaled Schoenfeld residuals on chosen functions of time, such as the logarithm or the rank of observed event times, or the Kaplan-Meier estimate of the survival function. For example, the test proposed by Harrell,^[17] which uses the correlation between the unscaled residuals and the rank of the event times, is similar to a trend test applied to the plot of the scaled residuals vs. the rank of the event times. The function cox.zph in S-Plus implements the score test developed by Grambsch and Therneau^[16] using the scaled Schoenfeld residuals, which is based on an extension of the Cox model to include time-varying regression coefficients. An overview of this test, as well as illustrations, can be found in Hosmer and Lemeshow^[18] (Section 6.3).

Martingale Residuals

The construction of *martingale residuals*^[19,20] is based on a *counting process*^[6,21] representation of the Cox model. The method relies heavily on probability theory and stochastic processes, and will not be discussed here. The residual for the i th individual is defined as:

$$m_i = \delta_i - \exp(\hat{\beta}^T x_i) \hat{\Lambda}_0(t_i) \quad (14)$$

which can be interpreted as the difference between the observed number of events for the individual over the interval $(0, t_i)$, and the predicted number of events in that interval under the fitted Cox model. To see this, note that the observed number of events is one if the event time is uncensored, and zero if censored, which is equal to the value of δ_i . The second term in Eq. 14 is an estimate of the cumulative hazard function at time t_i , which can be viewed as the expected number of events over $(0, t_i)$.

Despite the similarity, in terms of interpretation, between the martingale residuals and the residuals encountered in linear regression analysis, the distribution of the martingale residuals does not aid in the assessment of the overall fit of the Cox model in the usual manner. For example, a common diagnostic tool in linear regression analysis is the plot of the residuals against the fitted values; if the model is adequate, the points should scatter in a nonsystematic way. This plot is useless for martingale residuals because they are negatively correlated with the fitted values.

Martingale residuals are useful for investigating the appropriate functional form for a given covariate using an assumed Cox model for the remaining covariates. Technical details are provided in Fleming and Harrington^[6] (Section 4.5). Therneau and Grambsch^[8] illustrate the use of martingale residuals with examples.

EXTENSIONS

Time-Dependent Covariates

At the introduction of the proportional hazards regression model, Cox noted that the covariates for any given individual may be *time-dependent* or *time-varying*, that is, the values of the covariates may change over time. The resulting model is often referred to as the *extended Cox model*.

Time-dependent covariates are usually classified as being either *internal* or *external*.^[11] An internal time-dependent covariate is one whose value is specific to the individual, such as blood pressure of a patient recorded at different times. It is measured only as long as the individual is still under observation, and thus its value carries information about the event time of the individual. In contrast, an external time-dependent covariate is one whose value at a particular time does not require individuals to

be under observation, such as air pollution index for a particular geographic area recorded at different times.

Let $x_i(t) = (x_{i1}(t), x_{i2}(t), \dots, x_{ip}(t))^T$ denote the covariate values at time t for the i th individual under study, where $i = 1, 2, \dots, n$. The notation is general in the sense that if a particular covariate, say the k th covariate, is time-independent then $x_{ik}(t) = x_{ik}(0) = x_{ik}$. The partial likelihood function for data involving time-dependent covariates is similar to the expression in Eq. 6, with the appropriate alterations of x_i to $x_i(t)$. The estimation of the regression coefficients also proceeds as described in “Estimation.” It is not necessary to differentiate between internal and external time-dependent covariates in the construction of the partial likelihood or the estimation of the regression coefficients. The distinction, however, becomes important when the estimation of the survival function is of interest. For internal time-dependent covariates, $S(t|x_0(s), s \leq t) = 1$ because observing $x_0(t)$ indicates that the event has not occurred [because the individual could not have realized the event if $x_0(t)$ is observed]. The hazard function no longer bears a relationship to the survival function when internal time-dependent covariates are involved. Thus even though it is mathematically easy to extend the Cox model to include time-dependent covariates, one should examine the nature of any time-dependent covariate when interpreting the fitted model, especially when the absolute risk is of interest.

Frailty Models

In medicine, it is a common observation that the natural course of a disease or a treatment effect varies from individual to individual. This condition is often referred to as *individual heterogeneity*. It is rarely possible in practice to include all the relevant covariates to account for individual heterogeneity, either because we are not aware that there exist covariates to be included, or the heterogeneity is manifest only indirectly. The unmeasured covariates, when present in the usual linear model settings, are called *random effects*. Such covariates are called *frailties* in survival analysis, based on the idea that individuals have different frailties, and those who are most frail will experience an adverse event earlier than the others.^[22]

The Cox model can be extended in a natural way to account for individual heterogeneity, which may lead to more accurate estimates of β and $\lambda_0(t)$, and hence improvements in the predictions of relative and absolute risks. Let x_{i0} denote the value of an unmeasured covariate (the frailty) for the i th individual. The hazard function, conditional on both x_{i0} and $x_i = (x_{i1}, x_{i2}, \dots, x_{ip})^T$, becomes:

$$\lambda(t|x_i, x_{i0}) = \lambda_0(t) \exp(\beta_0 x_{i0} + \beta^T x_i) = w_i \lambda_0(t) \exp(\beta^T x_i) \quad (15)$$

where $w_i = \exp(\beta_0 x_{i0})$. Because $w_1, w_2, \dots, w_n$ are unobserved, they are viewed as a sample from some family of distributions with possibly unknown parameters.

The extended model, as expressed in Eq. 15, is called a *proportional hazards frailty regression model*.

Much of the research in proportional hazards frailty regression has dealt with the choice of a statistical distribution for the frailty. It is popular to let the frailty have a gamma distribution with a mean equal to one and an unknown variance γ . The resulting model is equivalent to the linear transformation model given in Eq. 4, with $g(\cdot) = -\log \Lambda_0(\cdot)$ and with ε having a $\text{Pareto}(\gamma)$ distribution. Other distributions proposed in the literature include the inverse Gaussian distribution,^[23] the positive stable distribution,^[24] and the log-normal distribution.^[25] Note that if the frailty distribution has zero variance, then Eq. 15 reduces to the Cox model; otherwise, a model with non-proportional hazards results. This implies that an estimate of the variance of the frailty distribution, which we shall denote as γ , is useful for assessing the proportional hazards assumption in the Cox model.

An estimation of model^[15] with γ assumed known has been studied extensively (e.g., Refs. [26,27]). These methods are not applicable when γ is unknown. Recently, Kosorok et al.^[28] developed a unified approach to estimation in model^[15] that allows for general frailty distributions with unspecified γ . The proposed algorithm permits inference about γ and β separately from the arbitrary $\lambda_0(t)$, as in the Cox partial likelihood approach. When the model is correctly specified, the procedure is semi-parametric efficient; moreover, the bootstrap gives valid inferences even under misspecification.

Protocol Development

Robert D. Chew

Pfizer Global Research and Development, Groton, Connecticut, U.S.A.

Abstract

The goal of this entry is to abstract the guidance published by the European Medicines Agency and the U.S. Food and Drug Administration as a convenience for the statistical practitioner faced with the task of describing in the protocol the planned analysis of a clinical trial and also to offer some suggestions based on practical experience in the field.

Keywords: Keywords: Clinical trial; Protocol development; Statistics.

INTRODUCTION

The goal of this entry is to abstract the guidance published by the European Medicines Agency (EMA) and the U.S. Food and Drug Administration (FDA)^[1-7] as a convenience for the statistical practitioner faced with the task of describing in the protocol the planned analysis of a clinical trial and also to offer some suggestions based on practical experience in the field.

The point of view here is confirmatory. Protocols are of course also produced for research trials, proof-of-concept trials, and the like. It is reasonable that such protocols might be less inclusive in terms of elements or less specific in terms of given elements. However it is also reasonable to suppose that any protocol might be made better, and certainly made no worse, by explicit consideration of the features of confirmatory trials during its preparation.

NATURE AND PURPOSE OF THE PROTOCOL FOR A CLINICAL TRIAL

The protocol for a clinical trial is “[a] document that describes the objective(s), design, methodology, statistical considerations, and organization of a trial.”^[1] It describes the medical conjecture, the subject population, the treatment regimens, the data gathering, and the analysis and evaluation of the data.

The primary purpose of this entry is to describe the function of the protocol as the portrayal of the statistical design and data analysis for a medical experiment. However, a clinical trial is a complex enterprise. The clinical-trials statistician should be aware that the protocol also serves a number of administrative and organizational purposes. As a document, the protocol is a contract between the sponsor and the investigator.^[1] The protocol identifies the agencies and individuals involved in the

project and describes their responsibilities and obligations (e.g., for serious adverse event reporting, availability of records for inspection). It serves as the primary means for the Institutional Review Board to ensure the ethical purpose and conduct of the trial and should contain a statement that the trial will be conducted in compliance with good clinical practice and the applicable regulatory requirements. The protocol summarizes the nature of the known and potential risks and benefits to the subjects. It requires informed consent and adherence to the principles in the Declaration of Helsinki. Certain sections of a protocol will typically contain instructions concerning the handling of specimens for laboratory analysis or the administration of special (or even routine) medical procedures.

Most institutions, and nearly all pharmaceutical companies, have standard outlines and naming/numbering conventions for protocols. Sections generally include, but are by no means limited to, those in the following abbreviated list. There are a number of reasonable ways to organize these topics within the document, and different sponsors will choose different conventions. However, nearly everyone covers at least the following topics somewhere in their protocols.

- *Introduction:* Describes the test article, synthesizes what is known about its effects and previous research, and motivates the current project.
- *Objective:* Sharpens the medical conjecture.
- *Subject selection criteria:* Defines the subject eligibility criteria in such a way as to link to a target population of prospective users of the treatment and protect the safety of study subjects.
- *Study medication:* Thoroughly describes the test and control treatments, their packaging, and the mechanism for treatment masking.
- *Plan and procedures:* Lays out the schedule of visits, doses, tests, and evaluations to be performed on the subjects by the investigative staff, rules around discontinuing

subjects, reporting of serious adverse events, and administration of concomitant or rescue medication.

- *Efficacy and safety endpoints and criteria:* Describes the primary and secondary efficacy and safety endpoints and how those data are going to be collected and scored. Study monitoring and data-collection quality controls might be described in this section.
- *Data analysis and statistical considerations:* Defines the primary and secondary variables; describes the primary and secondary analyses and the statistical design considerations.
- *Committees:* Identifies various committees associated with the trial and states their mission and scope. Examples would include data monitoring committees, endpoint classification committees, steering committees, and executive committees.^[2,4]
- *Pharmacoeconomic investigations:* Contains many of the same elements as the main protocol; often inserted as a subprotocol.
- *Pharmacokinetic/pharmacodynamic investigations:* Increasingly, population pharmacokinetics, exposure-response, and the like are included as secondary analyses in confirmatory trials; often inserted as a subprotocol.

Sponsors should have established procedures for generating, approving, and amending protocols. These procedures should state who is to be involved in the process and what role they are to play. The ICH Section E6 on Good Clinical Practice^[1] asserts that

[t]he sponsor should utilize qualified individuals (e.g., biostatisticians, clinical pharmacologists, and physicians) as appropriate, throughout all stages of the trial process, from designing the protocol and CRFs and planning the analyses to analyzing and preparing interim and final clinical trial/study reports.

It is a sound practice to require that the statistical section be contributed by a qualified professional statistician.

CONTENT OF THE STATISTICAL SECTION OF A PROTOCOL FOR A CLINICAL TRIAL

The advice of the ICH is to prespecify the analysis: “The extent to which the procedures in the protocol are followed and the primary analysis is planned a priori will contribute to the degree of confidence in the final results and conclusions of the trial.”^[3] Hence, the a priori specification of the analysis is an important function of the statistical analysis section of a protocol.

Primary Variable(s) and Analyses

“[T]he protocol should identify the primary [efficacy variables] with an explanation of why they were

chosen.”^[4] “Only results from analyses envisaged in the protocol (including amendments) can be regarded as confirmatory.”^[3]

Because most clinical trials collect a number of different types of variables, there will typically be a number of different analyses conducted on the data from a given trial. “The protocol should make clear a distinction between aspects of a trial that will be used for confirmatory proof and the aspects that will provide data for exploratory analysis.”^[3] One means of drawing this distinction, and of addressing the multiplicity issue besides, is via the definition, in the statistical section of the protocol, of a primary variable and a primary analysis. The terms *primary*, *secondary*, *exploratory*, and the like are probably not susceptible to rigorous definition. However, one sense in which those in the clinical-trials field tend to understand them is in terms of this confirmatory/exploratory distinction. The *primary* variable (or endpoint) is the variable in terms of which the investigators intend either to confirm or to refute the conjecture upon which the trial is based. Because it is often possible to analyze a given variable in a number of different ways, it is also recommended to specify a primary (stochastic) model and a primary analysis strategy for the primary variable.

What, then, is entailed in the specification of the primary variable and its analysis in the statistical analysis section of a protocol? Pharmaceutical trial statisticians have generally found the following set of considerations to be useful.

Primary Variable Definition

This is the precise mathematical definition of the primary outcome variable. In many instances this variable is not raw data but is derived according to some algorithm from the raw data. Stating that algorithm avoids ambiguity; e.g., say, “the return-visit-3 measurement minus the baseline-visit measurement as a percentage of the baseline” as opposed to, “the percentage change from baseline.” Mathematical notation is appropriate and useful; but it should be supplemented by a verbal description. Note that, in this example, there is an implicit understanding of the definition of *baseline*. It is usually helpful to state explicitly the definition of *baseline* and other time-point dependencies. They may not be as obvious as one might suppose.

Primary Statistical Objective

This involves a translation of the primary objective of the investigation into statistical terms: a statistical model and an accompanying hypothesis testing or estimation objective. If it is a hypothesis test, as is frequently the case, the null and alternative hypotheses should be stated in terms of the primary statistical model.

“It is vital that the protocol of a trial designed to demonstrate equivalence or noninferiority contain a clear statement that this is its explicit intention.”^[3,5]

Primary Analyses

These are the analyses, or statistics, that will produce the answers to the primary investigational conjecture. The ICH E9 document recommends that “all the principal features of the proposed confirmatory analysis of the primary variables”^[3] be laid out in the protocol. It is not unreasonable that different, equally competent analysts might make differing judgments about what is an appropriate level of analytical detail to include in a protocol, i.e., what constitutes a “principal feature” of the analysis. Further detail can be given in an accompanying analysis plan document. Most practitioners would state in the protocol the main statistic upon which the primary analysis will be based, e.g., least-squares means, log-likelihood ratio, some ranks-based test. If not pre-specified, covariate adjustments, variable transformations, and methods to handle dropouts or missing data can lead to controversy later. It is appropriate and useful to employ mathematical notation.

DECISION RULES

A description of the statistical decision space and decision rules is essential. “The protocol should... designate the pattern of significant findings or other method of combining information that would be interpreted as supporting efficacy.”^[4]

Given that one has calculated a set of statistics, one must state a priori how this set of statistics will be used to evaluate the primary conjecture. Whether hypothesis tests are one- or two-sided, their significance (alpha) levels, and/or outcomes that would lead the experimenters to conclude that treatments are equivalent, would be included with this topic. If a number of statistical hypotheses are being evaluated, give the map from the subsets of possible outcomes to the overall substantive conclusions.

Here, the rubric of analysis emphasizes the arithmetic, whereas the rubric of decision rule emphasizes the inference to be made from that arithmetic. It is useful, at least, to do the thinking around the analytic strategy in these terms.

ERROR CONTROL

The method for controlling the error rates must be set up. Particularly when a number of hypotheses are being tested, the method for controlling the Type I error rates, and at what level they will be controlled, should be stated. The method of management of the joint coverage probabilities

for sets of interval estimates would be given. Type II error rates might also be addressed.^[6]

ANALYSIS SUBSETS

A description of the subset of subjects whose data will contribute to the primary analysis should be included. This is where such terms as “Intention-to-treat,” “per-protocol,” and the like come in. It is advisable not to assume that all readers have the same understanding of these terms, but rather to explicitly spell out the membership requirements for (at least) the primary analysis subset.

DESIGN AND NUMBER OF SUBJECTS

The statistical aspects of the experimental design should be set out. This section gives the reasoning that justifies the planned number of subjects. Working estimates of anticipated treatment effects and variability would be given, along with their source. Clinically meaningful treatment effects that the study is targeted to detect or, in the case of equivalence trials, exclude, would be stated. If the design is something besides one-period, double-blind, parallel-group (e.g., a crossover or dose escalation), or if the design allows treatment transitions, then the statistical implications of these characteristics should be accounted for.

Sometimes trials are designed to be stopped when a certain amount of information has been accumulated. This is a statistical design feature that may not be obvious and ideally should be fully explained.

In a multicenter study, it may be useful to state the number of subjects planned per site.

SECONDARY VARIABLE(S) AND ANALYSES

“Secondary variables are either supportive measurements related to the primary objective or measurements of effects related to the secondary objective.”^[3] The testing of the primary efficacy conjecture in some subpopulation is a common secondary objective. Secondary endpoints can be defined, and their analyses planned, in an exposition that parallels that for the primary variables: variable definition, statistical model, statistical objective, analytic strategy, and decision rules. The level of detail for secondary analyses is frequently reduced, as compared to the primary analyses, and they can be discussed as a group in order to make the exposition efficient and readable. However, just as for primary analyses, it is obvious that the statement of secondary conjectures and analyses a priori is an important factor in lending credibility to the conclusions.

FURTHER TOPICS

Interim Analyses

The timing, purpose, and scope of planned interim analyses must be stated. If decisions about stopping the trial, extending the trial, or otherwise modifying the design (e.g., by adding or dropping treatment arms) are to be based on interim analyses, then the decision criteria should be described in the protocol. Spelling out comprehensively and in detail the process by which accumulating data will be examined and acted upon (or not) will obviate concerns about bias and scientific validity. This material could be rather extensive. See the entry titled *Interim Analysis* for further advice on what to include.

Randomization and Blinding

A high-level description of the randomization scheme might be included. It is not recommended that the block size be revealed in the protocol. A small proportion of trials have somewhat complex randomization schemes, and in these cases, the description would be appropriately more detailed. If the trial is not of the usual double-blind variety, then it may be helpful to argue for the type of treatment masking that is planned. The point is to address concerns that critics of the trial may raise regarding bias.

Problem Data

If it is possible to anticipate conditions under which data will be invalid or would otherwise create analytical challenges, then it may be worth describing them in the protocol and prespecifying analysis methods to account for the problem data. Outliers, missing observations, premature terminations, losses to follow-up, and protocol violations are some of the general categories of difficulties that can be anticipated. Another common issue is created by low-enrolling centers in a multicenter study where the analysis is blocked by center. Some sponsors may prefer to base their analytical approach to problem data on a treatment-masked review of the data conducted prior to any actual analysis. If methods for handling the problem data result from such a blinded pre-analysis review, and those methods are documented, then concerns around potential bias do not arise.

Because they can be rather intricate, details regarding the handling of problem data in the analyses are better left for the analysis plan rather than the protocol. However, the attention that the missing data problem

has received in recent years has created the expectation that the protocol for any confirmatory trial will include at least a high-level description of a strategy for dealing with missing data.^[7]

The ICH E9 document advises that “[t]he protocol should also specify procedures aimed at minimizing any anticipated irregularities in study conduct that might impair a satisfactory analysis.”^[3] This material may fit more naturally in the plan and procedures section of the protocol than in the statistical analysis section, however.

Safety Data

The planned analyses of safety data should be set out. According to conventions used by many sponsors, this description is terse, emphasizing summarization and display. However, if there are known safety issues, it is clearly in a sponsor's interest to prespecify in some detail an inferential strategy to address them. General analytical issues around safety data include the definition of incidence (per subject, per dose, per subject-year, etc.) and how to treat data from subjects who have no or minimal exposure to the study treatments.

P-Values

Stephen Senn

Department of Statistics, University of Glasgow, Glasgow, U.K.

Abstract

A *p*-value is the probability of observing a result as extreme or more extreme than that observed given that the null hypothesis is true. This entry reviews the history of *p*-values in research and discusses some of the issues and criticisms some researchers have in regards to *p*-values.

Keywords: Distribution; Jeffreys-Good-Lindley paradox; *P*-value.

INTRODUCTION

A *p*-value is the probability of observing a result as extreme or more extreme than that observed given that the null hypothesis (H_0) is true. To be able to calculate a *p*-value, one thus requires at least three things: a null hypothesis, a probability model, and an agreed ordering of the possible outcomes, so that those that are more extreme than those actually observed may be identified. This ordering is generally conveniently arranged in terms of a “test statistic” T so that higher or lower values of T , as the case may be, or higher absolute values (as perhaps in two-sided *p*-values) identify more extreme cases. In fact, the requirement to order the outcomes also generally entails a fourth requirement—that all possible relevant outcomes have been defined or restricted. These relevant outcomes form the so-called *sample space*. Usually, because *p*-values are a frequentist concept, the sample space is defined in terms of the possible outcomes that could occur from an infinite repetition of the experiment (e.g., a clinical trial).

In practice, it often turns out to be far from simple to agree what exactly such an infinite repetition would look like. For example, the trial protocol may not have fixed exactly in advance the number of patients on each arm, even if the trial is not a sequential trial; yet except where the trial is a sequential trial, generally no account is taken of this. In the analysis of binary data, a 2×2 table is often formed, and it is common (but not uncontroversial) to condition on both margins, even though one of them will not have been fixed at all in advance and even though the other may only have been fixed approximately.

These and other difficulties, which will be discussed in due course, mean that *p*-values have been a critical failure. However, if frequency of use is any guide, they have also been a huge popular success. It seems that *p*-values, despite having been banned by at least one journal, are here to stay for the foreseeable future.

HISTORY

David,^[1] in an article attempting to trace the first use of statistical terms, could find no use of the term “*p*-value” earlier than that of Brownlee^[2] in 1960. However, similar phrases were certainly used by Fisher^[3] as early as 1922 (e.g., “values of P ”) and the first use of the *concept* is often dated to be at least two centuries earlier than that, with the famous significance test of Arbuthnot.^[4] According to Arbuthnot, “Among innumerable Footsteps of Divine Providence to be found in the Works of Nature, there is a very remarkable one to be observed in the exact Balance that is maintained, between the numbers of Men and Women.” Arbuthnot had data on the christening of male and female children from London for the years 1629–1710. In each of these years, there was an excess of male christening, which he took to reflect an excess of births, which excess he regarded as necessary to compensate for higher male mortality. He then proceeds to calculate the probability of such a result occurring by chance. Observing that there is a finite but small probability of an exact equality of the sexes, Arbuthnot makes a conservative concession to what we would now call the “null hypothesis” by assuming that the probability of an excess of male births in a given year is 0.5. He then argues that the probability of such an excess 82 years in row is $(1/2)^{82}$, “which will be found easily by the Table of Logarithms to be 1/48360 0000 0000 0000 0000 0000,” going on to conclude, “from whence it follows that [it] is Art, not Chance, that governs.”

Arbuthnot’s probability can clearly be interpreted as a *p*-value but it is an atypical representative of the species because Arbuthnot has the most extreme case—all years show an excess of male births.^[5] In fact, Arbuthnot’s probability can be given two further alternative interpretations. Because it only reflects the observed result (and does not include more extreme cases), it is also a likelihood. In fact, as a function of the value of the probability

of the parameter in question—the probability of an excess of males births in a given year, say θ —and assuming a Bernoulli process, we have the likelihood as $L(\theta) = \theta^{82}$, which Arbuthnot merely calculated as $L(1/2)$. Yet another interpretation can be given. If Divine Providence is intervening to maintain the excess of male births, then the likelihood of observing such an excess is 1. Thus the ratio of likelihoods for the observed data given the hypothesis of “chance” (under Arbuthnot’s assumption) to that given the hypothesis of Divine Providence is also given by the probability calculated by Arbuthnot.

An early example of a p -value that incorporates the more usual difficulty of having to be calculated when the most extreme chance has not occurred is given in the prize-winning essay of Daniel Bernoulli^[6] in 1734. This considers, among other matters, whether the then known (six) planets had orbits that were coplanar to a degree that cannot be explained by chance. Bernoulli looks at this question in a number of different ways. One of these compares the planetary orbits to the sun’s equator with the following results:

Mercury	2°56′
Venus	4°10′
Earth	7°30′
Mars	5°49′
Jupiter	6°21′
Saturn	5°58′

The most extreme of these is that of the Earth at 7°30′. Because the maximum possible is 90°, this is $7°30′/90° = 1/12$. Bernoulli then argues that the probability that all six planets have inclinations to the sun’s equator of less than 7°30′ is $(1/12)^6 = 1/2985984$, thus concluding that this is no coincidence.

Bernoulli’s example has more difficulties than Arbuthnot’s example. He does not have the most extreme case and is thus on the horns of a dilemma. Either he would have to conclude that the pattern is uninteresting (the theory of exact coplanar orbits being clearly falsified), or he has to include the more extreme cases, otherwise he would get the same answer whatever the arrangement. For instance, if the precision to which the planetary orbits can be measured is 1 min, or $1′/90° = 1/5400$, then the probability of any observed arrangement is simply $(1/5400)^6 \simeq 1/(2.5 \times 10^{22})$ so that if a small probability of the observed result were a reason for rejecting the null hypothesis, it would be rejected whatever the result. This particular difficulty is one that critics of the p -value have repeatedly stressed.

If we turn to the more recent history of p -values, then Fisher is often credited (or blamed) for their popularity. This appears to be a result of his espousal of significance tests, with which p -values are often regarded as being closely associated. There are several problems with this view, however. The first is that tail area probabilities (for that is what p -values are) were calculated long before Fisher. Indeed,

they were used by both Student^[7] and Pearson,^[8] both of whom were Bayesians, and the latter gives them the modern interpretation of the probability of a result as extreme or more extreme than that observed. The second reason is that it was actually Fisher, together with Yates in their joint tables, who introduced the habit of inverse tabulation using fixed percentage points such as 5%, 1%, etc.^[9] This accords more easily with the practice of noting whether a result is or is not significant at a given significance level than with calculating the tail area probability. The third reason is that there is no unique association between p -values and the Fisherian significance test to the exclusion of the Neyman-Pearson hypothesis testing framework. As Lehmann,^[10] writing within the latter framework, puts it:

“In applications there is usually available a nested family of rejection regions, corresponding to different significance levels. It is then good practice to determine not only whether the hypothesis is accepted or rejected at the given significance level, but also to determine the smallest significance level $\tilde{\alpha} = \tilde{\alpha}(x)$, the significance probability or p -value, at which the hypothesis would be rejected for the given observation.”

Whatever the reason, whoever is or are historically responsible for promoting p -values as an inferential device, their widespread use cannot now be denied. For example, although there have been considerable efforts in recent years by medical statisticians to promote the use of confidence intervals when reporting the results of clinical trials^[11] and although others have suggested how Bayesian approaches might be employed,^[12] it is still the case that the overwhelming proportion of papers published in the medical literature will not only use p -values but will also give them pride of place in both abstract and report. This is true despite the fact that research has shown that physicians do not even understand how p -values are defined, let alone their properties.^[13,14] Some of these properties are examined below.

DISTRIBUTION OF THE P-VALUE

Under the null hypothesis, when based upon a continuous statistic, the p -value has a uniform distribution $U(0,1)$ (see below), so that every value between 0 and 1 is equally likely. As Fisher^[15] noted in 1932, in the fourth edition of his famous book, *Statistical Methods for Research Workers*, it thus follows that minus twice the logarithm of the p -value has a chi-square distribution under the null hypothesis. This can be used to combine the results of independent tests to perform a sort of meta-analysis (to use a more modern term), because if k in such log-transformed p -values is added, the distribution is χ^2_{2k} .

Where a problem is well structured in the sense that a model is specified up to an unknown parameter θ , then likelihood is a far superior device to the p -value for examining the support afforded by the data to different possible

values of θ . Even in the less well-structured case where the model has one or more nuisance parameters, the profile likelihood will form a better way of investigating support for given values of θ . Nevertheless, if for no other reason than that their use is so common, it is useful to get some general feelings for the distribution of the p -value under the family of alternative hypotheses, as it increases understanding of the way p -values behave and thus serves as a warning against rash interpretation. A number of authors have looked at this (e.g., Refs. 16–19), but it is implicit in many older Bayesian criticisms of p -values.^[20,21]

Take a simple but unrealistic case, which can nevertheless act as an approximation to many more realistic cases, where T is distributed normally with known standard error σ_T and unknown mean $E(T) = \theta$. We assume that under H_0 , $\theta = 0$. Suppose, most simply, that we are interested in a one-sided p -value and suppose without further loss of generality that we regard lower values of T as more “extreme.” (In the hypothesis testing framework, this would apply if we had as alternative hypothesis $H_1: \theta < 0$.) As a function of an observed value t of T , the p -value is then defined as $P(t) = P(T < t | \theta = 0)$. In this case, we have:

$$P(T < t | \theta = 0) = P(T/\sigma_T < t/\sigma_T | \theta = 0) = \Phi(t/\sigma_T) = \Phi(z)$$

where $\Phi(\cdot)$ is the distribution function of the standard normal and z is the ratio of statistic to standard error, which will have the standard normal distribution under H_0 . If Z is a random standard normal deviate, then its probability density function (pdf) is $\phi(z)$, where $\phi(\cdot)$ is the pdf of the standard normal. On the other hand, under the alternative hypothesis, we require:

$$\begin{aligned} P(T < t | \theta = \Delta) \\ &= P\{(T - \Delta)/\sigma_T < (t - \Delta)/\sigma_T | \theta = \Delta\} \\ &= \Phi(t/\sigma_T - \Delta/\sigma_T) = \Phi(z - \Delta/\sigma_T). \end{aligned}$$

so that the pdf of Z is:

$$\phi(z - \Delta/\sigma_T) \quad (1)$$

However, if $P = \Phi(z)$ is the p -value, then we have $dz = dP/\phi(z)$, $z = \Phi^{-1}(P)$ so that making the necessary substitutions in Eq. 1, we have the pdf of P as:

$$\frac{\phi\{\Phi^{-1}(P) - \Delta/\sigma_T\}}{\phi\{\Phi^{-1}(P)\}} \quad (2)$$

which is clearly equal to 1 when the null hypothesis is true and hence $\Delta = 0$.

It may be instructive to reparameterize Eq. 2 in terms of the power $\Psi(\Delta, \sigma_T)$ of a significance test associated with a given significance level α . We then have:

$$\Psi(\Delta, \sigma_T) = P\{T/\sigma_T < \Phi^{-1}(\alpha) | \theta = \Delta\} = \Phi\{\Phi^{-1}(\alpha) - \Delta/\sigma_T\}$$

which we may solve for Δ/σ_T to obtain:

$$\Delta/\sigma_T = \Phi^{-1}(\alpha) + \Phi^{-1}(\beta) \quad (3)$$

where $\beta = 1 - \Psi$ is the “Type II error rate.” Substituting Eq. 3 in Eq. 2, we obtain:

$$\frac{\phi\{\Phi^{-1}(P) - [\Phi^{-1}(\alpha) + \Phi^{-1}(\beta)]\}}{\phi\{\Phi^{-1}(P)\}} \quad (4)$$

Fig. 1 illustrates the probability density of the p -value for different values of the type I error rate (“size”) and

Fig. 1 Probability density (logarithmic axis) of the P -value (for a limited range 0–0.1) for trials with differing power for a size of 2.5%

power. It should be noted that as the power increases, for any p -value, however small, eventually a point will be reached where the result is more probable under the null hypothesis than under the alternative hypothesis. In the family of curves represented in Fig. 1, the break-even point is reached when the power is 97.5% for a test with 2.5% size and the p -value is observed to be exactly 0.025. (For the higher power of 99%, the pdf is actually lower under the alternative hypothesis rather than the null hypothesis.) This is because where the Type I and Type II error rates are identical to the p -value, the point estimate must be halfway between the clinically relevant difference and zero and thus gives equal “support” to these two.

An alternative way of looking at this is to consider the likelihood for a given p -value and predetermined size as a function of the power. We may do this by taking the pdf given by Eq. 4 and considering this as a function of $1 - \beta$ for a given P rather than as a function of P for a given β . (The size and power together merely determine the noncentrality parameter so that this is simply another way of looking at the likelihood as a function of the noncentrality parameter. However, although it is revealing to look at the likelihood of the p -value to gain theoretical understanding, in practice, such analysis should never be performed on the p -value scale.)

A family of curves is given in Fig. 2. The curves all correspond to p -values that would conventionally be considered significant, the least significant being $P = 0.025$. Initially, as the power increases, the likelihood increases. However, eventually a point is reached where the likelihood declines so that a given p -value, however significant, offers less plausible support for the clinically relevant difference

than for the null hypothesis if obtained from a very large trial. This point is at the heart of an important Bayesian criticism of p -values that will be considered in “Some Criticisms.” However, before it is considered, one red herring must be disposed of.

It is sometimes claimed that a significant result is more convincing if it comes from a very large trial than from a small one.^[22] This would appear to contradict the message of Fig. 2, which suggests that a given p -value, especially if marginally significant, might be less convincing from a large trial than a small one. In fact, there is no contradiction. Two different things are being discussed.^[19,23] The one is a statement of the form $P \leq 0.05$; the other is a statement of the form $P = 0.049$ (say). The situation is that in the former case, if this is all that is known (so that, for example, the statement $P \leq 0.05$ does not imply $0.01 \leq P \leq 0.05$ because if $P \leq 0.01$, this would have been stated),^[24] the result is more convincing with increasing sample size. This is because, for a given alternative, the likelihood of the observed result is, effectively, the power function. It is, of course, trivially true that power increases with increasing power. However, for the latter case, the likelihood is not the same as the power and hence the situation illustrated in Fig. 2 is obtained.

SOME CRITICISMS

In this section, some criticisms (mainly Bayesian) of the p -value are considered. The first relates closely to the discussion above.

Fig. 2 Log likelihood (scaled to be zero at maximum) as a function of power for a size of 0.025 (one-sided) for three different observed P -values

Jeffreys-Good-Lindley Paradox

As illustrated above, a consideration of the likelihood of a given p -value shows that, eventually, as the sample size increases, more support is given to the null hypothesis than for any given value under the alternative hypothesis. However, because the alternative hypothesis will typically comprise an (often open) interval of values, it does not at all follow that the parameter value under the null hypothesis will be better supported than for every parameter value under the alternative. On the other hand, the null may be better supported than most values under the alternative. This is the basis of the Bayesian criticism that eventually as the sample size increases, a given p -value is less indicative of the falsity of the null and may eventually support it.^[20,21,25] Below, a simplified version of this paradox is presented.

Consider, for example, Eq. 2 not as a function of P but as a function of Δ , so that it forms a likelihood for Δ . Under H_0 , $\Delta = 0$, and Eq. 2 = 1 so that the ratio of the likelihood for some given value under the alternative hypothesis is also equal to Eq. 2. However, $\phi(\cdot)$ is the pdf of a standard normal, and this reaches its maximum when the argument is zero so that because the denominator is constant, Eq. 2 is maximized when:

$$\begin{aligned}\Phi^{-1}(P) - \Delta/\sigma_t &= 0 \\ \Delta &= \sigma_t \Phi^{-1}(P)\end{aligned}\quad (5)$$

at which point it equals:

$$\frac{\phi(0)}{\phi\{\Phi^{-1}(P)\}}\quad (6)$$

This expression depends on P alone and so is constant for a given P , whatever the power of the test, and would appear to give support to what has been referred to as the “alpha postulate”: equal p -values from different trials given equal evidence against the respective null hypotheses. For example, if $P = 0.025$ (one-sided), the value of Eq. 6 is ≈ 6.8 .

However, if one were to adopt a Bayesian perspective, then one would have to consider the prior probability of a given alternative hypothesis. These prior probabilities qua prior probabilities do not change as data are obtained (it is not permitted to change one’s prior beliefs) so that the fact that there is always one possible value under the alternative hypothesis that remains better supported than the null hypothesis is not directly relevant. If this value is itself a priori unlikely—but others which receive little support from the data are more likely given that the alternative hypothesis is true—then the alternative hypothesis as a whole may not be well supported.

If one wishes to choose between what Cox has referred to as a *precise* hypothesis,^[26] which is to say a null hypothesis that specifies some precise value for the unknown

parameter (say $\Delta = 0$), and an *alternative* hypothesis that merely specifies a range for the parameter, say $\Delta > 0$, then a simple ratio of the form given by Eq. 4 is not appropriate. It is necessary to integrate the likelihood over the region of the hypothesis first.

Consider, for the moment, a common two-sided testing problem and suppose now that we believe with probability θ that H_0 : $\Delta = 0$ and hence believe with probability $(1 - \theta)$ that H_1 : $\Delta \neq 0$. Conditional on H_1 , we have a prior distribution for Δ which is $n(0, \gamma^2)$. Suppose that we run a trial that will yield a standard error for our test statistic T of σ_t and that we observe t to within a precision of $\pm \epsilon$. Our predictive distribution for $T = t$ given H_0 is $n(0, \sigma_t^2)$, so that the conditional probability of the observed result is approximately:

$$2\phi\left(\frac{t}{\sigma_t}\right)\frac{\epsilon}{\sigma_t}\quad (7)$$

On the other hand, conditional on H_1 , the distribution is $n(0, \sigma_t^2 + \gamma^2)$ so that we have a conditional probability of:

$$2\phi\left(\frac{t}{\sqrt{\sigma_t^2 + \gamma^2}}\right)\left(\frac{\epsilon}{\sqrt{\sigma_t^2 + \gamma^2}}\right)\quad (8)$$

The ratio of Eqs. 7–8 is the factor:

$$\frac{\phi(t/\sigma_t)}{\phi(t/\sqrt{\sigma_t^2 + \gamma^2})} \frac{\sqrt{\sigma_t^2 + \gamma^2}}{\sigma_t}\quad (9)$$

by which the prior odds in favor of H_0 , $\theta/(1 - \theta)$, must be multiplied in order to obtain the posterior odds. This is the product of two ratios. For a given P value, which implies a given value of t/σ_t , the first term approaches a limit, which is the ratio of the probability density at the observed standardized value to the value at 0. However, the same is not true of the second ratio. As the size of the trial increases, σ_t reduces, but γ^2 is unaffected and so the second term of Eq. 9 can be made arbitrarily large as the trial increases, and hence the factor by which the posterior odds will be increased, arbitrarily large.

VIOLATION OF THE LIKELIHOOD PRINCIPLE

The likelihood principle, originally due to Barnard,^[27] states (roughly) that evidence about an unknown parameter in a model depends on the data only through the likelihood. This means that the stopping rule is irrelevant. However, in applying hypothesis tests to sequential trials, it is usual to adjust the conclusion according to the stopping rule. Thus such sequential analyses (obviously) violate the likelihood principle as do hypothesis tests (at least to the extent that they are given evidential interpretations) and hence p -values.

This is a simple example from Pawitan.^[28] Compare a binomial and a negative binomial experiment to examine an unknown probability θ of success X , each with eight successes out of 10 trials. For the binomial experiment, $n = 10$ was fixed but for the negative binomial experiment, it was determined in advance so that the trial would stop as soon as there were two failures. The likelihood in both cases is: $L(\theta) = k\theta^8(1-\theta)^2$ where k is some constant that does not depend on θ . Under the likelihood principle, inferences in the two cases would be the same given identical prior distributions.

However, if we test $H_0: \theta = 0.5$, then although the p -value is given by $P(X \geq 8 | \theta = 0.5)$, the calculation is not the same in the two cases. For the binomial, we have:

$$P_{\text{bin}} = \sum_{x=8}^{10} \binom{10}{x} \left(\frac{1}{2}\right)^{10} = 0.055$$

However, for the negative binomial, we have:

$$P_{\text{neg}} \sum_{x=8}^{\infty} (x+1) \left(\frac{1}{2}\right)^{x+2} = 0.02$$

Thus because we have the same likelihoods but different p -values, there is a clear violation of the likelihood principle. The implication of this would seem to be (at the very least) that where we have well-structured models, likelihood is preferable as a means of forming inferences about the unknown parameter. This would only leave two justifications, if at all, for using p -values. The first is where the problems are so poorly structured that it is not possible to form a likelihood. (Daniel Bernoulli's would be one, for example, where it appears very difficult.) The second case would be as a means of helping to calibrate the likelihood in multiparameter models, likelihood being difficult to interpret under such cases. It may be noted that, in fact, a common practice in sequential trials is not to adjust the p -value for repeated significance tests but to adjust the reference level to which the p -value is referred. In fact, defining p -values in a way that reflects adjustment directly can be extremely difficult as the ordering of the sample space can be quite complex.

REPEATABILITY OF P-VALUES

A practical question of some interest in the context of drug development is what is the probability of repetition of the p -value. For example, given the observation $P = 0.05$ in trial 1, what is the probability that $P \leq 0.05$ in trial 2? Goodman^[29] has shown that this is plausibly about 50%. A very simple intuitive understanding why this is so may be gained by considering that if the median for the predictive probability distribution for the point estimate from the second trial is the point estimate from the first trial, then there is 50% probability that second point estimate will be

closer to the null than was the first. However, if the trial is the same size, the standard error will be similar so that there is half a chance that the standardized value will be less than it was before. But because it was just significant from the first trial, there is a 50% probability that it will not be significant from the second.

This is a practical point that should be better understood, but it is not, contrary to what has been claimed, an inferential weakness of p -values for a number of reasons.^[30] The first is that there is nothing special from the inferential point of view of looking at the predictive probability for a trial to follow of exactly the same size. If the trial is much larger, then the probability of significance is also larger. The second reason is that if it were the case that a significant result carried with it a high probability that a further result would also be significant, then anticipated evidence would have the same value as actual evidence, a paradoxical and unsatisfactory state of affairs. In fact, in this respect, the behavior of p -values closely resembles Bayesian probability statements.^[30]

ISSUES AFFECTING THE USE OF P-VALUES IN PRACTICE

In this section, some practical issues that affect the use of p -values are discussed. The first is particularly relevant to their use in drug development.

Two-Trials Rule

It is unusual in the context of drug regulation that a pharmaceutical sponsor will achieve the registration of a pharmaceutical by presenting the results of a Phase III program, which only contains one significant trial. A convention, which is usually but not universally observed, has arisen over the years that two Phase III trials should be significant. In the simplest case, where there are only two trials in the Phase III program, because the conventional level of significance employed is $0.025 = 1/40$ one-sided and if the results from both trials are regarded as trustworthy, the overall Type I error rate for the program becomes $(1/40)^2 = 1/16000 = 0.00625$. If this were the only purpose of the two-trials rule, the regulator could be provided with equivalent protection by running a single trial and requiring $P < 0.00625$, one-sided.^[19,31]

To get some feel for this alternative requirement, we may consider the unrealistic but instructive case where data from the two trials we would run are homogenous, the variance is known a priori, and the trials are of identical design and size. If we use the common two-trials rule, we require that the z -scores z_1, z_2 , which is to say the standardized differences from trials 1 and 2, should be less than -1.96 so that we have $z_1 \leq -1.96$. However, the sum $z_1 + z_2$ has a variance of 2 and a standard error of $\sqrt{2}$ and because the quantile of the standard normal corresponding

to 0.00625 is -3.227 , this alternative requirement would have $z_1 + z_2 \leq -3.227\sqrt{2} = -4.564$.

Note that if this alternative requirement is adopted, then individual p -values of 0.025 one-sided will no longer produce significance. The minimal p -value requirement that would *guarantee* significance if both trials satisfied it would now be one corresponding to $\Phi(-4.564/2) = \Phi(-2.282) = 0.011$. On the other hand, there is no requirement for both p -values to attain this limit because significance attained in one is traded off against the other.

However, this alternative approach (which is almost identical, under these circumstance, to an analysis of the pooled data fitting trial as a block) would be more efficient. The only advantage of the common current approach would be if one feared that every now and then circumstances would arise to make a trial result unusable. If that is feared, however, the very common current practice of running two similar trials with almost identical protocols recruiting similar patients in similar centers makes no sense.^[19]

Other Approaches to Combining P-Values

Where a number of trials has been carried out, it may sometimes (rather rarely in practice) be desirable to combine

the results using p -values alone. Fisher's approach has already been discussed above. An early alternative proposal is that of Tippet, which simply uses the minimum p -value to judge the significance of the result. If k trials are being combined, then the probability under H_0 that the minimum p -value is at least as low as the observed minimum value is:

$$P_{\text{Tippet}} = 1 - (1 - P_{\min})^k \quad (10)$$

This is a slightly sharper adjustment than the common Bonferroni adjustment of $kP_{\min}$ for target significance for multiplicity because it exploits the independence of the p -values under the null for a series of trials.^[32] Yet another approach is to base a test on the sum (or equivalently the average) p -value.^[33]

Fig. 3 illustrates the contours of “global” p -values for four of these schemes for the case where there are two trials. However, in practice, meta-analytic approaches using original data are superior and because the sponsor usually has access to all data, there is no reason to summarize the results of a drug development using a direct combination of p -values.^[34]

Fig. 3 Contour plots of global P -values calculated from individual P -values from two trials according to four different methods

One-Sided or Two-Sided *P*-Values

The usual convention in drug regulation is that a result is accepted as significant when the two-sided *p*-value is less than 0.05. In practice, however, the regulator will not register a new drug if it is significantly worse than the comparator, whether this is a placebo or a standard treatment. Consequently, one might suppose that if θ represents the difference between the experimental drug and the comparator (defined in such a way that low values of θ are “good”), then in a hypothesis testing framework, the practical problem is to decide between pairs of hypotheses: $H_{0A} : \theta = 0, H_1 : \theta < 0$ or, more realistically, between: $H_{0B} : \theta \geq 0, H_1 : \theta < 0$. This corresponds to a one-sided testing situation and hence one might suppose that one-sided *p*-values would be more appropriate.

To the extent that two-sided *p*-values are calculated by doubling the one-sided *p*-value, this makes no difference because the values commonly adopted for significance are merely conventional. Faced with a sponsor who wished to use one-sided *p*-values, the regulator could accede to the request but then simply insist on using 2.5% as the threshold for significance. The practical effect would be the same as using a 5% one-sided test.

A technical difficulty and possible inferential controversy arises when using test statistics whose distribution is not symmetric.^[28] For example, suppose we want to test whether the mean λ of a random variable X with a Poisson distribution is equal to 13, against the hypothesis that it is not. We take a single observation and observe $X = 6$. The exact one-sided *p*-value is $P(X \leq 6 | \lambda = 13) = 0.0259$. If we double this, we get $P = 0.052$. However, we could instead consider what would constitute a value as extreme or more extreme in the other direction. There are various ways we could define extreme. One might be on the basis of the ratio of the likelihood given the maximum likelihood estimate to the likelihood under the null. This, for given $X = x$, is $LR = e^{x-\lambda}(\lambda/x)^x$ and for the observed value of six this yields 10.6. However, for $x \geq 22$, $LR \geq 13.1$, whereas for $x \leq 21$, $LR \leq 7.9$ so that values of $x \geq 22$ should lead to rejection of the hypothesis. However, $P(X \geq 22) = 0.014$ so that using an approach of adding together tail areas, one would have $P = 0.026 + 0.014 = 0.04$.

This difficulty must be counted as a further inferential drawback of *p*-values. In practice, a rule that has many advantages is simply to double the one-sided value when a two-sided value is wanted.^[35]

A Bayesian examination of *p*-values is given by Freedman^[36] who concludes that there is really no justification from this perspective for two-sided *p*-values.

Problems with Discrete Data

Part of the problem with the Poisson case above concerns the asymmetry of the distribution. However, a further part of it has to do with the discrete nature of the data.

This causes difficulties for hypothesis testing also in that a particular target Type I error rate (say 5%) may not be attainable unless, as part of the decision rule, an auxiliary randomization device were used.^[37] For instance, returning to the Poisson distribution of the previous example, suppose we are interested in testing the alternative $\lambda < 13$. If we reject if $X \leq 7$, the Type I error rate is 0.054, whereas if we reject if $X \leq 6$, we have an error rate of 0.026 (as discussed above). However, suppose we have an auxiliary random variable $R, U(0,1)$, a device first suggested by Tocher,^[37] note that $(0.05 - 0.026)/(0.054 - 0.026) = 0.86$. The following rule will give a Type I error rate of 5%: reject if $(X \leq 6)$ or $(X = 7 \cap R \leq 0.86)$. Of course, in practice, no regulator will accept such an arbitrary external randomizing device but it should be noted that methods, such as hypothesis testing, which themselves make use of the sample space to make decisions, use a partially arbitrary internal randomization device (see Ivanova and Berger^[38] for a particularly marked example). Be that as it may, it is at least a theoretical possibility in the hypothesis testing framework and one which has at least one possible application, namely that of comparing different tests in terms of power in a way that avoids distortion because of particular significance levels that one test or the other test could attain.^[39]

If it seems repugnant to use an auxiliary device for testing hypotheses, it will seem even more so for calculating *p*-values. However, the analogous strategy would appear to be to calculate the probability of observing a result just more extreme than that observed and add some random fraction of the probability of the result observed. Clearly, in practice, no one will do this. However, alternatively, if one imagines that a “remote scientist,” who may have a different habitual Type I error rate to the trialist, would like to use one’s own auxiliary device, one will need to provide two *p*-values: $P(T \leq t)$ and $P(T < t)$, where t is the observed value of the test statistic T . These two *p*-values are sometimes used to calculate a third value, as will now be explained.

The “lumpiness” of testing that accompanies discrete data carries over into *p*-values. In particular, where combining *p*-values is important, this can be unfortunate. However, the distributional properties of *p*-values can be improved by calculating a so called mid P ^[40,41] as $\{P(T \leq t) + P(T < t)\}/2$. This has theoretical advantages over the classical *p*-value for this purpose but in practice is little used.

Multiplicity

Where many significance tests are being performed at a common level of α , the probability of at least one being significant is greater than α . If it is desired to control this family-wise Type I error rate, then it will be necessary to adopt some special scheme, perhaps a predefined order of tests, some adjustment downward of target levels of significance or some adjustment upward of *p*-values.

This is a vast and controversial topic.^[42,43] There is no general agreement that such adjustments are sensible. However, of all the approaches, the upward adjustment of p -values seems the least satisfactory in that it is the one that makes it most difficult for any “remote scientist” to come to an independent inference.

Adaptive Designs

In recent years, there has been a great deal of interest in adaptive designs starting with the influential paper in 1994 by Bauer and Kohne^[44] which used approaches to combining p -values as the basis for controlling the type I error rate. Because p -values, rather than more conventional test statistics are used, such approaches can be extremely flexible since one can even change the outcome measure between different stages of a design. The approach is not without its critics since it can (in theory) do considerable violence to the likelihood principle. A critical evaluation is given by Burman and Sonneson.^[45]

CONCLUSION

A possible historical interpretation is that p -values represent a way of discussing compatibility between null hypotheses and data, which, although not without logical difficulties, is so intuitively appealing that scientists in all areas have tended to use them. Just how natural this way of thinking is may be illustrated using an example from a paper criticizing p -values. In his interesting article, Matthews not only urges scientists to abandon p -values but also considers some aspects of scientific honesty and reporting. In discussing Millikan’s famous determinations of the charge of the electron he writes, “the discrepancy is so large that the probability of generating it by chance alone is less than 1 in 10^3 .”^[46] However, he might just as well have written $P < 0.001$ because this is exactly what is reported here.

It seems that p -values are one of the ways we choose to look at data and models: the most popular and the least respectable. They are perhaps the “pulp fiction” of statistical inference—shallow but not completely without merit. However, there is no denying that they can be dangerous, that where we have well-structured problems, we can do far better, and that the current degree of reliance on them in medical research and drug development is to be deplored.

FURTHER READING

There is a very extensive literature critical of p -values. The papers by Berger and Berry,^[47] Freeman,^[48] Goodman,^[49] and Matthews^[46] are particularly readable introductions. See also papers by Johnstone^[50] and particularly Berger and Sellke^[51] for more detailed criticisms.

Royall^[23] specifically considers the effect of sample size on the meaning of p -values, a point that was famously dealt with by Lindley^[21] (but see Bartlett^[52] for a necessary correction). A classic paper proving the incompatibility of p -values and the likelihood principle is that of Birnbaum.^[53] An excellent and thorough overview of likelihood methods is the book by Pawitan.^[28] For a general discussion of the Bayesian and likelihood approaches to inference and the possible role (if any) of p -values, see the book by Good.^[25] An important paper discussing the use of significance tests in general is that of Cox^[26] and an examination from a Bayesian perspective with particular attention to one-sided and two-sided tests is provided by Freedman.^[36]

There are rather fewer papers defending p -values. Barnard^[40] (despite being the author of the likelihood principle) finds a limited use for them. Senn^[54,55] gives a lukewarm defense. Whitmore and Xekalaki^[56] consider an extension of the p -value concept to consider the predictive validity of models. One of the best discussions of approaches to combining p -values from a number of trials is the article in German by Sonneman.^[32] Another important paper on this topic is that of Birnbaum.^[57]

Abstract

This entry summarizes four prescribed QT analysis methods and compares them in terms of their biases and efficiencies in QT and QTc prolongation estimations are compared theoretically, and also discusses clinical trial design issues.

INTRODUCTION

Cardiac repolarization is a normal, physiologic process that occurs in man by the outward movement of potassium ions through specific channels in myocardial cell membranes. An undesirable feature of some pharmaceutical agents is their ability to delay cardiac repolarization, an effect that can be indirectly measured as prolongation of the QT/QTc interval on the surface electrocardiogram (ECG). The QT/QTc interval (Fig. 1) represents the time duration of ventricular depolarization and subsequent repolarization, beginning at the start of the QRS complex and ending where the T wave returns to isoelectric baseline. A delay in cardiac repolarization (as manifested by QT prolongation) can predispose to the development of life-threatening cardiac arrhythmias [e.g., torsade de pointes (TdP)]. TdP may degenerate into ventricular fibrillation leading to sudden death.

Most drugs that have caused TdP (fatal and nonfatal) associated with the use of a drug have resulted in regulatory actions, including withdrawal from the market (e.g., terfenadine and cisapride), restriction of use (e.g., thioridazine and droperidol), or denial of marketing authorization. To regulate QT/QTc interval prolongation assessment in non-clinical and clinical trials, Food and Drug Administration (FDA) is announcing the availability of a guidance entitled “E14 Clinical Evaluation of QT/QTc Interval Prolongation and Proarrhythmic Potential for Non-Antiarrhythmic Drugs.”^[1] The guidance was prepared under the auspices of the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH). The guidance provides recommendations to sponsors concerning clinical studies to assess the potential of a new drug to

cause cardiac arrhythmias, focusing on the assessment of changes in the QT/QTc interval on the ECG as a predictor of risk. The guidance is intended to encourage the assessment of drug effects on the QT/QTc interval as a standard part of drug development.

This E14 ICH guideline^[1] provides recommendations to sponsors concerning the design, conduct, analysis, and interpretation of clinical studies to assess the potential of a drug to prolong the QT/QTc intervals. More detailed statistical reviews on design and analysis of QT/QTc data are described in the report from Pharmaceutical Manufacturers and Research Association (PhRMA) Statistics Expert Team.^[2] We briefly summarize some important aspects. In designing a QT trial, both positive and placebo controls are important for showing effect or no effect; replicated QT ECGs at a specific time help to reduce the within-subject variation, hence increase the power; the collections of baseline ECGs from multiple resources are more reliable than using a single baseline ECG data set; a definitive QT/QTc study should generally provide dose-response information, including the effect at dose higher than those anticipated for therapeutic purpose; and the choice of end points (QTc prolongation or above/below a QTc threshold) should be dictated by the primary objective of the study, as well as different analyses performed to achieve that objective.

In analyzing QT/QTc data, because of its inverse relationship to heart rate, the QT interval is routinely transformed (normalized) by means of various formulae into a heart rate-independent “corrected” value known as the QTc interval. Two common heart rate correction methods used in clinical practice are Bazett’s^[3] correction and Fridericia’s^[4] correction. By convention, these two correction methods correct the QT interval to a standard heart rate of 60 bpm. However, it has been

Fig. 1 The P wave represents depolarization occurring within the atria of the heart. The QRS complex represents depolarization occurring within the ventricles of the heart. The T wave represents repolarization occurring within the ventricles of the heart. The QT interval is the period of time it takes to complete both depolarization and repolarization within the ventricles and is measured from the beginning of the Q wave to the end of the T wave

recognized that the relationship between heart rate and QT interval is individual specific. Thus the application of a population level correction such as Bazett's or Fridericia's may not be optimal to correct heart rate in a specific individual and may increase variability when analyzing data. Malik^[5] proposed to characterize an individual's QT/RR relationship obtained from off-drug or placebo data, and then apply subject-specific correction factors derived from the off-drug data to the on-drug dataset. However, because this method assumes an unchanged QT/RR relationship after the drug treatment, it could lead to a biased QTc prolongation estimate. This problem was addressed by Li et al.^[6] in a joint QT correction for both off- and on-drug data.

In this article, for the first time, four prescribed QT analysis methods are summarized together. Their biases and efficiencies in QTc and QTc prolongation estimations are compared theoretically. Their performances are illustrated through a haloperidol QT analysis. In addition, clinical trial design issues are discussed, specifically crossover vs. parallel group studies.

ANALYSIS OF ECG DATA FROM CLINICAL TRIALS

QT Correction Method Overview

Historically, QT analysis is usually composed of two steps.^[3,4] Malik^[5] gives us a comprehensive review of this topic. The first step is to correct the QT interval for the effect of heart rate (inverse of RR interval). Heart rate correction of the QT interval can be based

on a uniform correction for all subjects or based on a subject-specific correction derived from individual regression analysis of that subject's placebo (off-drug) QT vs. RR data. The second step in analyzing whether a drug-induced QT interval change has occurred is to perform statistical analyses based on the heart rate corrected QT (QTc) between the treatment (on-drug) and placebo (off-drug) groups.

From a statistical perspective, it is clear that a one-step joint statistical model for both on- and off-drug QT analysis justified by RR intervals would be the method of choice. As linear mixed models^[7] and nonlinear mixed models^[8] have become popular tools for many biomedical researches, this QT analysis is a simply problem. However, because clinical pharmacologists would be more comfortable with a two-step analysis, it is important to determine to what extent that the two-step analysis would lose information or be biased relative to the one-step joint analysis. Although this problem is discussed in detail before,^[6] this entry provides a comprehensive summary of various QT analysis.

There are many proposed heart rate QT correction methods cited in the medical literature. What is considered the best method of correction is debatable. Bazett's formula^[3] is by far the most common correction used by clinicians, because it is practical and convenient. Based on his empirical experience, Bazett assumed the following relationship $QT = \alpha \times RR^{1/2}$, and $QTc = QT \times 1000^{1/2}/RR^{1/2}$.

QTc has the interpretation of QT when RR = 1000 ms. Fridericia's^[4] formula is another commonly used QT correction method and has been suggested by some to be a better alternative to Bazett's method. He proposed a different empirical model, $QT = \alpha \times RR^{1/3}$, and $QTc = QT \times 1000^{1/3}/RR^{1/3}$. Neither method acknowledged the variation of the QT vs. RR relationship from population to population or subject to subject. Hence, corrected QT inevitably has large variations. The limitations of these uniform corrections were evaluated by Malik^[5] and Desai et al.^[9,10]

Malik^[5] recognized the limitation of assuming a constant relationship between QT vs. RR among different individuals and proposed a subject-specific model to correct the QT interval at the first step through Eqs. (1) and (2). The subject-specific $\hat{\beta}_i$ is a least square estimate of β_i from Eq. (1) that utilized the off-drug (placebo) QT and RR data from subject i only

$$QT_{ij} = \alpha_i \times RR_{ij}^{\beta_i} + \varepsilon_{ij} \quad (1)$$

$$QTc_{ij} = QT_{ij} \times 1000^{\hat{\beta}_i} / RR_{ij}^{\hat{\beta}_i} \quad (2)$$

Although Malik's method has greatly improved the subject-wise QT correction, it has three potential limitations. Firstly, the validity of the equal variance assumption for the measure error of a QT interval is questionable. Based

on our experience, the variance of a QT interval is usually proportional to its magnitude. A better alternative model is a linear model for the log-transformed QT and RR, which is described in Eq. (3). More detailed discussion of the variance model and transformation can be found in Carroll and Ruppert.^[9]

$$\log \text{QT}_{ij} = \gamma_i + \beta_i \times \log \text{RR}_{ij} + \varepsilon_{ij} \quad (3)$$

Secondly, subject-specific estimate of $\tilde{\beta}_i$ in Eq. (2) may not be practical, because it can often be difficult to acquire such large numbers of ECGs (e.g., 41) in a single subject^[5] during a pharmacokinetic/pharmacodynamic study. Although Malik's method can provide asymptotically unbiased subject-specific estimate of β_i , it has larger variance than the best linear unbiased prediction of β_i based on the log-likelihood function for Eq. (1) or (3). This property was carefully addressed in both linear mixed models^[7] and non-linear mixed models.^[8]

Thirdly, at step one, Malik's QT correction term $\tilde{\beta}_i$ in Eq. (2) is estimated from the placebo (off-drug) group only. It is equivalent to assume that β_i is unchanged on and off the drug, which may or may not be true. Hence, the bias of the QTc prolongation estimates caused by this assumption violation needs to be justified. The first two limitations can be addressed by well-developed linear and non-linear mixed model theories, while the third assumption was addressed by Li et al.^[6]

In this section, theoretical comparisons among three methods are performed: fixed coefficient QT corrections proposed by Bazett and Fridericia (fixed QTc), off-drug only QT correction proposed by Malik (off-drug QTc), and off-on-drug joint QT correction proposed by Li et al.^[6] (off-on QTc). The biases and efficiencies of these QTc methods on QTc and QTc prolongation estimates will be derived.

Model Specification

We chose $\log(\text{QT})$ as the outcome variable because QT is often modeled as a power function of RR in the literature.^[5] Log transformation can render a linear relationship. In addition, as the measurement error of the QT interval usually has a constant coefficient of variation (CV), a log transformation can make the variance homogeneous. Davidian and Carroll^[11] provided detailed discussion of the model and transformation of the non-constant variance. It has been shown that women differ from men with regard to the QT vs. RR relationship at heart rates below 100 (or $\text{RR} < 600$ ms) with women having greater QTc prolongation for any given heart rate,^[12] and it is well known that gender can influence drug-induced QTc changes.^[13] Therefore, $\log(\text{QT})$ and $\log(\text{RR})$ should have different linear relationships for the males and the females.

The statistical literatures on linear mixed models can be traced back at least as far as Harville^[14] and Laird and Ware.^[15] Those models have been broadly applied to the biomedical research. Eq. (4) is a linear mixed model representation, where $y_{p,gij}$ denotes the $\log(\text{QT})$ measurement during the placebo period for subject i of gender g at the time point t_j , $g = 1$ (male), 2 (female), $i = 1, \dots, m$ and $j = 1, \dots, n$. Similarly, $y_{t,gij}$ is the $\log(\text{QT})$ measurement during the treatment period for subject i at the time point t_j . The terms, $x_{p,2gij}$ and $x_{t,2gij}$, denote the $\log(\text{RR}/1000)$ measurements within the placebo and treatment periods, respectively. The $\log(\text{RR})$ is linearly transformed to $\log(\text{RR}/1000)$ because the intercept has the heart rate corrected $\log(\text{QT})$ or $\log(\text{QTc})$ interpretation when $\text{RR} = 1000$ ms in model (4). In addition, $x_{p,1gij}$ and $x_{t,1gij}$ are the indicator variables for the gender. In model (4), $\beta_{t,1g}$ and $\beta_{p,1g}$ are $\log(\text{QTc})$ s (intercepts) for the treatment and placebo periods of gender g , respectively, $\beta_{t,2g}$ and $\beta_{p,2g}$ are two corresponding slopes between the $\log(\text{QT})$ and $\log(\text{RR})$. The errors, $\varepsilon_{t,gij}$ and $\varepsilon_{p,gij}$, are $i.i.d.N(0, \sigma_0^2)$, random effect follows $b_{1gi} \sim N(0, \sigma_1^2)$, b_{2gi} follows $N(0, \sigma_2^2)$, and $\text{corr}(b_{1gi}, b_{2gi}) = \rho$. Model (5) is a matrix expression of (4).

$$y_{t,gij} = x_{t,1gij}\beta_{t,1g} + b_{1gi} + (\beta_{t,2g} + b_{2gi})x_{t,2gij} + \varepsilon_{t,gij} \quad (4)$$

$$y_{p,gij} = x_{p,1gij}\beta_{p,1g} + b_{1gi} + (\beta_{p,2g} + b_{2gi})x_{p,2gij} + \varepsilon_{p,gij}$$

$$\begin{aligned} y_t &= x_{t,1}\beta_{t,1} + x_{t,2}\beta_{t,2} + z_{t,1}b_1 + z_{t,2}b_2 + \varepsilon_t \\ y_p &= x_{p,1}\beta_{p,1} + x_{p,2}\beta_{p,2} + z_{p,1}b_1 + z_{p,2}b_2 + \varepsilon_p \end{aligned} \quad (5)$$

$$\begin{aligned} \text{cov}(b_1) &= I\sigma_1^2, \text{cov}(b_2) = I\sigma_2^2, \quad \text{cov}(b_1, b_2) = I\rho\sigma_1\sigma_2 \\ \text{cov}(\varepsilon_t) &= \text{cov}(\varepsilon_p) = I\sigma_0^2 \end{aligned}$$

The QTc is defined as the QT when $\text{RR} = 1000$ ms. In terms of our model (4), the true QTc in the treatment and placebo periods for the males and females are:

$$\begin{aligned} \text{true_QTc}_{t,\text{male}} &= e^{\beta_{t,11}}, \quad \text{true_QTc}_{t,\text{female}} = e^{\beta_{t,12}} \\ \text{true_QTc}_{p,\text{male}} &= e^{\beta_{p,11}}, \quad \text{true_QTc}_{p,\text{female}} = e^{\beta_{p,12}} \end{aligned} \quad (6)$$

The null hypotheses are $\text{true_QTc}_{t,\text{male}} = \text{true_QTc}_{p,\text{male}}$ and $\text{true_QTc}_{t,\text{female}} = \text{true_QTc}_{p,\text{female}}$. Particularly, $\text{true_QTc}_{t,\text{male}} - \text{true_QTc}_{p,\text{male}}$ and $\text{true_QTc}_{t,\text{female}} - \text{true_QTc}_{p,\text{female}}$ represent the QTc prolongations owing to the treatment for the males and females, respectively.

Fixed QT Correction Analysis

In Bazett and Fridericia's correction formula,^[3,4] the QT correction coefficients owing to RR are 0.33 and 0.50, respectively. Here we would like to investigate their QTc and QTc prolongation's biases and variances. Denote β^F as

a vector of fixed QT correction coefficients. The corrected log(QT) for both treatment and placebo groups is:

$$\begin{aligned} y_t^F &= x_{t,1}\beta_{t,1} + x_{t,2}(\beta_{t,2} - \beta^F) + z_{t,1}b_1 + z_{t,2}b_2 + \varepsilon_t \\ y_p^F &= x_{p,1}\beta_{p,1} + x_{p,2}(\beta_{p,2} - \beta^F) + z_{p,1}b_1 + z_{p,2}b_2 + \varepsilon_p \end{aligned} \quad (7)$$

In the analysis step, by assuming that the slopes of log(QT) vs. log(RR) to be β^F on and off the drug, and there is no subject to subject variation, some terms in (7), $x_{t,2}(\beta_{t,2} - \beta^F)$, $z_{t,2}b_2$, $x_{p,2}(\beta_{p,2} - \beta^F)$, and $z_{p,2}b_2$ are zeros. Thus the model can be expressed in Eq. (8), where $\text{cov}(a_i) = I\tau_i^2$, and $\text{cov}(e_i) = \text{cov}(e_p) = I\tau_0^2$. In particular, $\eta_{t,1} - \eta_{p,1}$ is the log(QTc) prolongation based on the mis-specified model (8).

$$\begin{aligned} y_t^* &= x_{t,1}\eta_{t,1} + z_{t,1}a_1 + e_t, \\ y_p^* &= x_{p,1}\eta_{p,1} + z_{p,1}a_1 + e_p \end{aligned} \quad (8)$$

The restricted maximum likelihood (REML) of $(\eta_{t,1}^T, \eta_{p,1}^T)^T$ from (8) is $(\tilde{\eta}_{t,1}^T, \tilde{\eta}_{p,1}^T)^T = (x_1^T w x_1)^{-1} x_1^T w y^F$, where $w = (\tau_0^2 I + \tau_1^2 z_1 z_1^T)^{-1}$, $x_1 = \text{diag}(x_{t,1}, x_{p,1})$, and $z_1 = (z_{t,1}^T, z_{p,1}^T)^T$. On the other hand, $(\tilde{\eta}_{t,1}^T, \tilde{\eta}_{p,1}^T)^T$ can be expressed in terms of (9) and (10) from its true model (7)

$$\begin{pmatrix} \tilde{\eta}_{t,1} \\ \tilde{\eta}_{p,1} \end{pmatrix} = \begin{pmatrix} c_0^{-1}c_{11} & 0 \\ 0 & c_0^{-1}c_{22} \end{pmatrix} \times \begin{pmatrix} x_{t,1}\beta_{t,1} + x_{t,2}(\beta_{t,2} - \beta^F) + z_{t,1}b_1 + z_{t,2}b_2 + \varepsilon_t \\ x_{p,1}\beta_{p,1} + x_{p,2}(\beta_{p,2} - \beta^F) + z_{p,1}b_1 + z_{p,2}b_2 + \varepsilon_p \end{pmatrix} \quad (9)$$

$$\begin{aligned} \tilde{\eta}_{t,1} - \tilde{\eta}_{p,1} &= c_0^{-1} \left(c_{11}x_{t,1}\beta_{t,1} - c_{22}x_{p,1}\beta_{p,1} \right) \\ &\quad + c_0^{-1} \left[c_{11}x_{t,2}(\beta_{t,2} - \beta^F) \right. \\ &\quad \left. - c_{22}x_{p,2}(\beta_{p,2} - \beta^F) \right] \\ &\quad + c_0^{-1} (c_{11}z_{t,1} - c_{22}z_{p,1})b_1 \\ &\quad + c_0^{-1} (c_{11}z_{t,2} - c_{22}z_{p,2})b_2 \\ &\quad + c_0^{-1} (c_{11}\varepsilon_t - c_{22}\varepsilon_p) \end{aligned} \quad (10)$$

Taking expectation on both sides of (9) and (10), Eqs. (11) and (12) display the quantities that fixed QT correction method estimates. Apparently, the estimate of log(QTc) is biased according to Eq. (11). The bias, the second terms of Eq. (11), comes from the products of $\bar{x}_{t,2}$ and $(\beta_{t,2} - \beta^F)$ in treatment group, and $\bar{x}_{p,2}$ and $(\beta_{p,2} - \beta^F)$ in placebo group, where $(\bar{x}_{t,2}, \bar{x}_{p,2})$ represents the closeness of average RR measurements to 1000 ms. The covariance of $\tilde{\eta}_{t,1} - \tilde{\eta}_{p,1}$ is given in Eq. (13), its asymptotic approximation.

$$\begin{pmatrix} E(\tilde{\eta}_{t,1}) \\ E(\tilde{\eta}_{p,1}) \end{pmatrix} = \begin{pmatrix} \beta_{t,1} + \bar{x}_{t,2}(\beta_{t,2} - \beta^F) \\ \beta_{p,1} + \bar{x}_{p,2}(\beta_{p,2} - \beta^F) \end{pmatrix} \quad (11)$$

$$E(\tilde{\eta}_{t,1} - \tilde{\eta}_{p,1}) = (\beta_{t,1} - \beta_{p,1}) + (\bar{x}_{t,2}\beta_{t,2} - \bar{x}_{p,2}\beta_{p,2}) - (\bar{x}_{t,2} - \bar{x}_{p,2})\beta^F \quad (12)$$

$$\text{cov}(\tilde{\eta}_{t,1} - \tilde{\eta}_{p,1}) = O\{\Delta\bar{z}_2^2\} + O\left\{\frac{1}{mn}\right\} \quad (13)$$

$$\begin{aligned} \bar{x}_{t,2} &= \begin{pmatrix} 1/nm \sum_{ij} \log(\text{RR}_{t,21ij}/1000), & 0 \\ 0, & 1/nm \sum_{ij} \log(\text{RR}_{t,22ij}/1000) \end{pmatrix}, \\ \bar{x}_{p,2} &= \begin{pmatrix} 1/nm \sum_{ij} \log(\text{RR}_{p,21ij}/1000), & 0 \\ 0, & 1/nm \sum_{ij} \log(\text{RR}_{p,22ij}/1000) \end{pmatrix} \end{aligned}$$

$$\begin{aligned} \Delta\bar{z}_2^2 &= \left\{ \sum_i \left[\sum_j \log(\text{RR}_{t,21ij}/\text{RR}_{p,21ij})/n \right]^2 / m, \right. \\ &\quad \left. \sum_i \left[\sum_j \log(\text{RR}_{t,22ij}/\text{RR}_{p,22ij})/n \right]^2 / m \right\}^T \end{aligned}$$

Off-Drug QT Correction Analysis

The detailed off-drug QT correction analysis can be found in Ref. [6]. We present a summary here. In Malik's QT correction step, based on the placebo data, $y_p = x_{p,1}\beta_{p,1} + x_{p,2}\beta_{p,2} + z_{p,1}b_1 + z_{p,2}b_2 + \varepsilon_p$, the REML^[12] of $\beta_{p,2}$ and b_2 are $\tilde{\beta}_{p,2}$ and $\tilde{b}_2$, respectively. The corrected log(QT) for both treatment and placebo groups are:

$$\begin{aligned} y_t^* &= x_{t,1}\beta_{t,1} + x_{t,2}(\beta_{t,2} - \tilde{\beta}_{p,2}) + z_{t,1}b_1 \\ &\quad + z_{t,2}(b_2 - \tilde{b}_2) + \varepsilon_t \\ y_p^* &= x_{p,1}\beta_{p,1} + x_{p,2}(\beta_{p,2} - \tilde{\beta}_{p,2}) + z_{p,1}b_1 \\ &\quad + z_{p,2}(b_2 - \tilde{b}_2) + \varepsilon_p \end{aligned} \quad (14)$$

In the analysis step, by assuming unchanged slopes of log(QT) vs. log(RR) on and off the drug, some terms in Eq. (14), $x_{t,2}(\beta_{t,2} - \tilde{\beta}_{p,2})$, $z_{t,2}(b_2 - \tilde{b}_2)$, $x_{p,2}(\beta_{p,2} - \tilde{\beta}_{p,2})$, and $z_{p,2}(b_2 - \tilde{b}_2)$ are canceled out. Thus the model becomes Eq. (15), in which $\text{cov}(a_i) = I\tau_i^2$, and $\text{cov}(e_i) = \text{cov}(e_p) = I\tau_0^2$. In particular, $\eta_{t,1} - \eta_{p,1}$ is the log(QTc) prolongation based on the misspecified model (15) under the unchanged slope assumption.

$$\begin{aligned} y_t^* &= x_{t,1}\eta_{t,1} + z_{t,1}a_1 + e_t \\ y_p^* &= x_{p,1}\eta_{p,1} + z_{p,1}a_1 + e_p \end{aligned} \quad (15)$$

The REML of $(\eta_{t,1}^T, \eta_{p,1}^T)^T$ from Eq. (15) is $(\tilde{\eta}_{t,1}^T, \tilde{\eta}_{p,1}^T)^T = (x_1^T w x_1)^{-1} x_1^T w y^*$. Based on Li et al.^[6], their expectations are displayed in Eqs. (16) and (17). Apparently, treated group's log(QTc) estimate is biased, and the estimate of log(QTc) prolongation is biased. The bias, the second term of Eq. (17), comes from the product of $\bar{x}_{t,2}$ and $(\beta_{t,2} - \beta_{p,2})$. Eq. (18) provides log(QTc) prolongation estimate variance's asymptotic approximation.

$$E(\tilde{\eta}_{p,1}) = \beta_{p,1}, \quad E(\tilde{\eta}_{t,1}) = \beta_{t,1} + \bar{x}_{t,2}(\beta_{t,2} - \beta_{p,2}) \quad (16)$$

$$E(\tilde{\eta}_{t,1} - \tilde{\eta}_{p,1}) = (\beta_{t,1} - \beta_{p,1}) + \bar{x}_{t,2}(\beta_{t,2} - \beta_{p,2}) \quad (17)$$

$$\begin{aligned} \text{cov}(\hat{\beta}_{t,1} - \hat{\beta}_{p,1}) &= O\left\{\frac{1}{mn}\right\} + O\left\{\frac{\Delta \bar{x}_2^2}{mn}\right\} + O\left\{\frac{\Delta \bar{z}_2^2}{mn}\right\} \\ \Delta \bar{x}_2^2 &= \left\{ \left(\frac{1}{mn} \sum_{ij} \log(RR_{t,21ij} / RR_{p,21ij}) \right)^2 \right. \\ &\quad \left. \left(\frac{1}{mn} \sum_{ij} \log(RR_{t,22ij} / RR_{p,22ij}) \right)^2 \right\}^T \end{aligned} \quad (18)$$

Off-On-Drug QT Correction Analysis

Estimating the QTc from the joint models in (5) is called the off-on-drug QT correction analysis. Obviously all the β s in Eq.(5) can be estimated jointly by maximizing REML. Following the theories of linear models,^[7,16] the QTc prolongation estimates are unbiased and the most efficient. However, we would like to describe the REML from the joint models (5) as if they are solved through the following two-step procedure. This procedure provides us a way to compare the fixed QT correction analysis and off-drug QT correction analysis to the off-on-drug QT correction analysis. Given that $\hat{\beta}_{t,2}$, $\hat{\beta}_{p,2}$, and $\hat{b}_2$ are REML estimates of $\beta_{t,2}$, $\beta_{p,2}$, and b_2 from Eq. (5), respectively, the REML of $\beta_{t,1}$, $\beta_{p,1}$, and b_1 can be solved through a reduced model (19) by treating $\hat{\beta}_{t,2} = \hat{\beta}_{t,2}$, $\hat{b}_2 = \hat{b}_2$, and $\hat{\beta}_{p,2} = \hat{\beta}_{p,2}$.

$$\begin{aligned} y_t^{**} &= x_{t,1} \beta_{t,1} + x_{t,2} (\beta_{t,2} - \hat{\beta}_{t,2}) + z_{t,1} b_1 \\ &\quad + z_{t,2} (b_2 - \hat{b}_2) + \varepsilon_t \\ y_p^{**} &= x_{p,1} \beta_{p,1} + x_{p,2} (\beta_{p,2} - \hat{\beta}_{p,2}) + z_{p,1} b_1 \\ &\quad + z_{p,2} (b_2 - \hat{b}_2) + \varepsilon_p \end{aligned} \quad (19)$$

In particular, $(\hat{\beta}_{t,1}^T, \hat{\beta}_{p,1}^T)^T = (x_1^T w x_1)^{-1} x_1^T w y^{**}$, where $w = (\sigma_0^2 I + \sigma_1^2 z_1 z_1^T)^{-1}$, $x_1 = (x_{t,1}^T, x_{p,1}^T)^T$, $z_1 = (z_{t,1}^T, z_{p,1}^T)^T$, and $y^{**} = (y_t^{**T}, y_p^{**T})^T$. With the same derivations as in Eqs. (16) and (17), $E(\hat{\beta}_{t,1}) = \beta_{t,1}$, $E(\hat{\beta}_{p,2}) = \beta_{p,2}$, and $E(\hat{\beta}_{t,1} - \hat{\beta}_{p,2}) = \beta_{t,1} - \beta_{p,1}$.

They reinforce that REML estimate $\hat{\beta}_{t,1} - \hat{\beta}_{p,2}$ is unbiased. The asymptotic covariance of $\hat{\beta}_{t,1} - \hat{\beta}_{p,2}$ follows Eq. (20),

$$\text{cov}(\hat{\beta}_{t,1} - \hat{\beta}_{p,1}) = O\left\{\frac{1}{mn}\right\} + O\left\{\frac{\Delta \bar{x}_2^2}{mn}\right\} + O\left\{\frac{\Delta \bar{z}_2^2}{mn}\right\} \quad (20)$$

SUMMARY

- The fixed QT correction analysis leads to both biased log(QTc) and its prolongation estimates. The degree of bias for the log(QTc) estimates depends on $\bar{x}_{t,2}(\beta_{t,2} - \beta^F)$ in treatment group, and $\bar{x}_{p,2}(\beta_{p,2} - \beta^F)$ in placebo group; the degree of log(QTc) prolongation estimates depends on $(\bar{x}_{t,2}\beta_{t,2} - \bar{x}_{p,2}\beta_{p,2}) - (\bar{x}_{t,2} - \bar{x}_{p,2})\beta^F$. The variance of log(QTc) prolongation estimate is as the same order as $O\{\Delta \bar{x}_2^2\} + O\{1/mn\}$.
- Off-drug QT correction has unbiased log(QTc) estimate in placebo group, but bias estimate in treatment group. Thus, it leads to a biased log(QTc) prolongation estimate, and the bias is $\bar{x}_{t,2}(\beta_{t,2} - \beta_{p,2})$. The variance of log(QTc) prolongation estimate is as the same order as $O\{1/mn\} + O\{\Delta \bar{x}_2^2/mn\} + O\{\Delta \bar{z}_2^2/mn\}$.
- Off-on-drug method has no bias on log(QTc) and log(QTc) prolongation estimates. The variance of log(QTc) prolongation estimate is as the same order as $O\{1/mn\} + O\{\Delta \bar{x}_2^2/mn\} + O\{\Delta \bar{z}_2^2/mn\}$.

HALOPERIDOL DATA ANALYSIS

We studied 22 nonsmoking healthy volunteers aged between 21 and 41 years. The study was conducted in Georgetown University's General Clinical Research Center (GCRC). All volunteers gave written informed consent prior to participation in the study. The study protocol was approved by the Institutional Review Board of Georgetown University Medical Center. This protocol was a randomized, double blind, placebo controlled crossover clinical trial. There were two study periods with each period lasting four days. There was a three-day washout between the two study periods. Subjects were randomly assigned to receive either a single placebo capsule or a single haloperidol tablet (Geneva Pharmaceuticals Lot # 114748, Broomfield, CO) at 8 AM during the first study period and the alternative treatment at the identical time during the second study period. ECGs were collected before and 2, 4, 6, 8, 10, 24, 36, 48, 60, 72, 84, and 96 hr after the administration of either the placebo or haloperidol. A total of 13 recordings were performed in the placebo period and 13 recordings performed in the treatment period. ECGs were obtained with the subject resting supine for approximately 15 min prior to acquisition using a MAC 5000 ECG machine (GE Medical Systems, Milwaukee, WI). We acquired 12 lead ECGs

at a paper speed of 50 mm/sec and an amplitude of 20 mm/mV. The ECGs were printed in a format that displayed rhythm strips from all 12 leads simultaneously to facilitate identification of the earliest Q wave and latest T wave observable.

Fig. 2 shows the patterns of $\log(\text{QT})$ vs. $\log(\text{RR})$ relationships between the males and females in the treatment and placebo periods separately. The $\log(\text{QTc})$ is $\log(\text{QT})$ when $\log(\text{RR}) = \log(1000) \cong 6.91$. Fig. 3 shows the fitting of

Fig. 2 Plots of $\log(\text{QT})$ vs. $\log(\text{RR})$ (raw data). The solid lines are for males, and the dotted lines are for females. (A) is the placebo group and (B) is the treatment group

Fig. 3 Plots of $\log(\text{QT})$ vs. $\log(\text{RR})$ based the fitting of linear mixed models (3) and (4). The solid lines are for males, and the broken lines are for females. (A) is the placebo group and (B) is the treatment group

model (4) based on our method. Males and females have different QT vs. RR relationships in both the placebo and treatment periods. In addition, after treatment, male and female's QTc tend to be closer than they are in the placebo period. Table 1 summarizes the QT and QTc prolongation estimates among all four methods, Fridericia, Bazett, off-drug, and off-on-drug QT analysis.

- **QTc estimates:** Treatment does not alter the $\log(\text{QT})$ and $\log(\text{RR})$ relationships in both female and male groups according to our off-on-drug analysis, i.e., the slopes are 0.35 and 0.32 for treatment and placebo groups in male group, and they are 0.26 and 0.26 in the female group. As we expected, female and male have different QT/RR relationship. The off-on-drug correction term for male is more close to Fridericia coefficient (0.33) than Bazett's coefficient (0.50). Therefore, Fridericia's QTc estimates should be more close to off-on-drug QTc than Bazett's QTc estimates, and they are confirmed in Table 1. For example, in the treated female group, off-on-drug QTc is 419.17ms, Fridericia's QTc is 421.70 ms, and Bazett's QTc is 424.31ms. On the other hand, as the drug does not change the slope of $\log(\text{QT})$ and $\log(\text{RR})$ much, off-on-drug and off-drug QTc estimates are close. For example, in the treated female group, off-on-drug QTc is 419.17 ms and off-drug QTc is 420.35 ms.
- **QTc prolongation estimates:** Following our theoretical discussion, off-on-drug QTc prolongation

Table 1 Haloperidol Data Analysis

Parameter	Period	Sex	OFF-ON	OFF	Fridericia	Bazett

ρ			0.788	0.864		

OFF represents the off-drug QT correction analysis, OFF-ON represents the off-on drug QT correction analysis, and Fridericia and Bazett are fixed QT correction analysis.

estimate is unbiased, but the other three are biased. The bias largely depends on the difference between the estimated or fixed QTc correction slope and the true QTc correction slope. In off-drug analysis, as the difference of slopes between treated and placebo groups is small in both male and female groups, the off-drug QTc prolongation estimates have small biases. For example, in the female group, the off-drug QTc prolongation is estimated as -1.66 ms, and the off-on-drug estimate is -1.56 ms. On the other hand, as Fridericia's slope, 0.33, is closer to the ones from off-on method than Bazett's 0.50, Bazett's QTc prolongation estimate, 1.07 ms, is more biased than the Fridericia's -0.87 ms.

- **Variance of QTc prolongation estimates:** Both two fixed coefficient methods have larger standard errors (SEs) than the regression based methods, i.e., 1.47 ms (Fridericia) and 1.88 ms (Bazett) vs. 1.38 ms in both off-on-drug and off-drug. These results confirmed our asymptotic approximations in Eqs. (13), (18), and (20).

CLINICAL TRIAL DESIGN AND SAMPLE SIZE CONSIDERATION

Clinical Trial Design

There are many clinical trial design elements to consider when designing a study to assess the ability of a pharmaceutical agent to prolong the QT interval. Some of these elements include selecting the most appropriate dose or doses to study, appropriate timing of ECG measurements, appropriate blinding, the use of a positive control agent to demonstrate assay sensitivity, and appropriate powering of the study.

With respect to study power and adequately sizing a study, it is important to identify a clinically irrelevant (or clinically relevant) magnitude of QT/QTc interval prolongation. It is not completely clear what magnitude of QT/QTc interval prolongation is of no clinical consequence. It has been suggested by some that drugs that prolong the mean (baseline and placebo-subtracted) QTc interval by 5 ms or less do not appear to cause TdP.^[15]

Table 2 Power and Sample Size Analysis

Total sample 2 <i>mn</i>	Number of subject <i>m</i>	QT#/subject <i>n</i>	QTc prolongation			
			5 <i>ms</i>	10 <i>ms</i>	20 <i>ms</i>	40 <i>ms</i>
200	100	1	0.047	0.057	0.185	0.890
400	200	1	0.051	0.074	0.455	0.992
600	300	1	0.059	0.115	0.690	1.000
800	400	1	0.061	0.201	0.840	1.000
1000	500	1	0.066	0.262	0.911	1.000
1200	600	1	0.069	0.340	0.975	1.000
200	20	5	0.057	0.167	0.487	0.950
300	30	5	0.097	0.227	0.628	1.000
400	20	10	0.087	0.272	0.765	1.000
400	40	5	0.107	0.288	0.897	1.000
600	30	10	0.141	0.358	0.910	1.000
800	40	10	0.163	0.498	0.979	1.000

The number *m* denotes subject number in a clinical trial, and *n* denotes the QT samples per subject. All the power calculations are based on 10,000 simulation data sets.

One design topic that is discussed in more detail in this review deals with the use of a crossover or parallel group design. We will see later in section 5 that parallel group design usually needs more samples (QT measurements) than crossover design, because the crossover design uses within-subject variation more efficiently.

Crossover or parallel group study designs can be suitable for trials assessing the potential of a drug to cause QT/QTc interval prolongation. Crossover studies at least have two potential advantages:

- They usually call for smaller numbers of subjects than parallel group studies, as the subjects serve as their own controls and hence reduce variability of differences related to intersubject variability.
- They might facilitate heart rate correction approaches based on individual subject data.

Parallel group studies might be preferred under certain circumstances:

- For drugs with long elimination half-lives for which lengthy time intervals would be required to achieve steady state or complete washout.
- If carryover effects are prominent for other reasons, such as irreversible receptor binding or long-lived active metabolites.
- If multiple doses or treatment groups are to be compared.

Power and Sample Size Analysis

Following our discussion in the clinical trial design, it is worthwhile to provide more details in crossover and parallel designs. According to the variation information we obtained from the data analysis, it would be very helpful

to investigate the sample size and power in testing QTc prolongation hypotheses.

In the simulation, the within-subject CV for QT is $\sigma_0 = 0.026$, the between-subject CV at the average level (random intercept) for QT is $\sigma_1 = 0.32$, and the between-subject standard deviation for log(QT) and log(RR) slope is set as $\sigma_2 = 0.057$. The slope is set as $\beta_{21} = 0.33$ for both placebo and treated groups. For the sake of simplicity, we treat male and female subjects equally. Practically, they do show different QTc and log(QT) and log(RR) relationship, but they only take two degrees of freedom to estimate them, and won't affect the sample size much. The simulated data for both crossover and parallel designs are generated through model (21) and (22), in which, dQTc is the QTc prolongation that we expect to detect from the data. In our simulation, dQTc is specified as 5, 10, 20, and 40 ms. Different sample size combinations for subject number, $m = (20, 30, 40)$, and samples per subject, $n = (1, 5, 10, \text{ and } 15)$ are simulated. Please note that, *m* denotes the number of subjects in each treatment group. The total QT sample size is 2 *mn*.

$$\begin{aligned} \log(\text{QT})_{t,ij} &= \beta_{t,1} + b_{1i} + (\beta_{t,2} + b_{2i}) \\ &\quad \log(\text{RR}_{t,2ij}/1000) + \varepsilon_{t,ij}, \\ \log(\text{QT})_{p,ij} &= \beta_{p,1} + b_{1i} + (\beta_{p,2} + b_{2i}) \\ &\quad \log(\text{RR}_{p,2ij}/1000) + \varepsilon_{p,ij} \end{aligned} \quad (21)$$

$$\begin{aligned} \text{cov}(b_{1i}) &= 0.032^2, \quad \text{cov}(b_{2i}) = 0.057^2, \\ \text{corr}(b_{1i}, b_{2i}) &= 0.85, \\ \text{cov}(\varepsilon_t) &= \text{cov}(\varepsilon_p) = 0.026^2, \quad \beta_{t,2} = \beta_{p,2} = 0.33, \\ \beta_{t,1} &= \log(420 \text{ ms} + \text{dQTC}), \quad \beta_{p,1} = \log(420 \text{ ms}), \\ (\text{RR}_{t,ij}, \text{RR}_{p,ij}) &\sim N[\log(1000 \text{ ms}), 160^2] \end{aligned} \quad (22)$$

When there are more than one QT sample measured from each subject in a clinical trial (i.e., crossover trial), off-on QTc analysis will be performed. For parallel group trial, in which only one QT sample is measured for a subject, a linear model (23) is employed to test the QTc prolongation hypothesis. In this linear model (23), $e_{t,i}$ contains both within-subject variation, $\varepsilon_{t,i}$, and between-subject variations (b_{1i} , b_{2i}).

$$\begin{aligned}\log(\text{QT})_{t,i} &= \beta_{t,1} + \beta_{t,2} \log(\text{RR}_{t,2i}/1000) + e_{t,i}, \\ \log(\text{QT})_{p,i} &= \beta_{p,1} + \beta_{p,2} \log(\text{RR}_{p,2i}/1000) + e_{p,i}\end{aligned}\quad (23)$$

Each power in Table 2 is calculated from 10000 simulation data sets.

In summary:

- Parallel design requires larger samples (QT measurements) than crossover design to achieve the similar power. For example, for $d\text{QT}_c = 10$ ms, parallel design needs 1200 samples to achieve 34% power, while crossover design needs only 600 samples to achieve 35.8% power. For $d\text{QT}_c = 20$ ms, parallel design needs 1000 samples to achieve 91% power, while crossover design needs only 600 samples to achieve 91% power.
- In the crossover design, when the total sample size is fixed, less samples per subject tend to provide more power than more samples per subject. For example, for $d\text{QT}_c = 10$ ms, 20 subjects and 10-sample/subject provides 27.2% power; and 40 subjects and 5-sample/subject provides 28.8% power. For $d\text{QT}_c = 20$ ms, these two combinations give 76.5% and 89.7% power, respectively.

CONCLUSIONS

Fixed QT correction analysis, such as Bazett and Fridericia, not only have biased QTc prolongation estimates, but also lead to larger variances. Off-drug QT correction analysis proposed by Malik has small bias in QTc prolongation estimate. Its variance is almost the same as those based on off-on-drug correction analysis. Our proposed off-on-drug correction analysis has no bias in QTc and QTc prolongation estimates. Although the off analysis can produce reliable QTc prolongation estimates, off-on analysis is a better choice by all means. As the standard statistical softwares for linear mixed models, i.e., SAS PROC MIXED (SAS Institute) and Splunx nlme (Mathsoft Inc.), become more popular, we highly encourage scientists to implement the off-on analysis.

Generally crossover design needs smaller sample size than parallel design. In the crossover design, when the

total sample size is fixed, less samples per subject tend to provide more power than more samples per subject.

Although off-on analyses assumed a constant drug effect during the study, this assumption need not be true. If this assumption is not true, this analysis will yield a diluted drug effect on the QTc interval because drug concentrations at the very beginning and tail end of the study are much lower than during the middle of the study. This may be one reason that we failed to see a drug effect in females administered haloperidol in our study. Thus, modeling the QTc time profile and evaluating its association with the drug concentration are important clinical questions. Adding time effects and drug concentrations into the $\log(\text{QT})$ vs. $\log(\text{RR})$ model is not trivial work, because allowing both the intercept and slope of model (4) to be functions of time will greatly increase the colinearity. This can become a good research topic.

Quality by Design in Biopharmaceutical Development

Harry Yang

MedImmune, LLC, Gaithersburg, Maryland, U.S.A.

Abstract

In recent years Quality by design (QbD) has been in the forefront of biopharmaceutical development. A cornerstone of QbD is to build quality into a product based on a thorough understanding of the product and manufacturing process. To that end, QbD involves defining desired clinical performance, identifying critical quality attributes that have an impact on product safety and efficacy, determining necessary raw material attributes and manufacturing process parameters to achieve the desired product quality attributes, and designing manufacturing controls to ensure consistent manufacturing. QbD enhances development capability, increases development speed, and enables manufacturing robustness. It also helps proactively prevent manufacturing failures. In certain instances QbD enables a manufacturer to make post-approval changes or scale-up operations without prior approval from regulatory authorities. However, implementation of QbD is often challenging. This article discusses key elements of QbD and statistical methods that can be utilized to enable the successful implementation of QbD.

Keywords: Analytical method; Bayesian analysis; Critical quality attributes; Design space; Process validation; Quality-by-Design; Risk assessment.

INTRODUCTION

Quality by design (QbD) has been in the forefront of biopharmaceutical development ever since the publication in [year] by the US Food and Drug Administration (FDA) of “*Pharmaceutical Current Good Manufacturing Practices (cGMPs) for the 21st Century*.” This initiative was intended to address a number of issues concerning pharmaceutical industry, which include low efficiencies in bringing innovative medicines to the market, waste of materials, and rework of finished products. Coupled with other subsequent regulatory publications including ICH Q8 (R2) Pharmaceutical Development, ICH Q9 Quality Risk Management, ICH Q10 Pharmaceutical Quality Systems, and Q11 Concept Paper, the initiative paved the way for the industry to adopt a QbD approach to process and product development, utilizing new technological advances and quality risk management (QRM) techniques. To deliver on the promise of this initiative, an increased emphasis has been placed on product and process understanding. This includes understanding the mechanism of action of the product, its safety profile, variability of raw materials, bulk and finished products, analytical method variations, relationships between process parameters and the product’s critical quality attributes (CQAs), and the impact of specific CQAs on clinical responses and overall product quality. This enhanced product and process knowledge not only enables product quality to be built by

design, but also provides a basis for the development of robust control strategies.

However, despite the plethora of opportunities to reduce manufacturing costs while ensuring product quality, implementation of QbD is often challenging due to the large number of variables to consider, interactions among the variables, uncertainties in measurements, and missing data involved in product and process development. Such intrinsic complexities argue for advanced statistical methods in both study design and analysis. This article is intended to discuss key elements of QbD, statistical methods and other analytical tools that can be utilized to help with implementation of QbD.

QUALITY BY DESIGN

In the traditional development paradigm, product and process design are often based on studies that explore one variable at a time, resulting in little understanding of the interdependence of variables that may have a joint effect on an output. Process validation is traditionally a documentation exercise, and primarily focused on the initial full-scale batches from a process. The overall product quality demonstration relied on extensive testing, including the inspection of raw materials, in-process material testing, and final drug substance and product release testing. The lack of product and process understanding and limited

knowledge of variability of analytical methods and manufacture process often resulted in stringent specifications that prohibited the release of products that otherwise may have had acceptable clinical performance.^[1] As changes to the process and/or test methods required post approval submissions, there were no incentives for the manufacturers to improve their manufacturing processes.

The QbD approach distinguishes itself from the traditional product and process development paradigm in many aspects. Key to this is that quality should be designed into a product, rather than demonstrated by testing. Under QbD, product and process development begins with pre-defined quality objectives, followed by the identification of critical quality attributes (CQAs) that have a significant impact on the drug product. Experiments are carried out to understand process variability and establish the relationships between process performance and input materials and process parameters. This knowledge serves as the basis for developing effective process controls focused on the areas of high risk. It also lends the manufacturer the ability to develop a manufacturing process that is flexible and consistent in delivering high quality product.

As outlined in ICH Q8 (R2),^[2] key steps to the implementation of QbD include: (1) defining quality target product profile (QTPP); (2) determining CQAs through risk assessment; (3) linking raw material attributes (MAs) and process parameters (PPs) to CQAs; (4) developing design space for key MAs and PPs; (5) developing and implementing effective control strategies; and (6) managing the product life cycle through continued process improvement. The overall QbD approach is illustrated in Fig. 1. The successful implementation of QbD requires significant effort in each of the above steps and relies on novel applications of statistical methods.^[3]

Quality Target Product Profile

The quality target product profile (QTPP) defines a new drug product in terms of its desired quality characteristics, and serves as the focal point for the development of the product and for all stages of the product lifecycle. Specifically, the QTPP is defined by ICH as “[a] prospective summary of the quality characteristics of a drug product that ideally will be achieved to ensure that the desired quality, taking into account safety and efficacy of the drug product.”^[2] ICH Q8 (R2) also lists some considerations for the QTPP, including: “Intended use in clinical setting, route of administration, dosage form, delivery systems; Dosage strength(s); Container closure system; Therapeutic moiety release or delivery and attributes affecting pharmacokinetic characteristics (e.g., dissolution, aerodynamic performance) appropriate to the drug product dosage form being developed; and Drug product quality criteria (e.g., sterility, purity, stability and drug release) appropriate for the intended marketed product.”^[2] While all of these aspects need to be taken into account, more attention may

Fig. 1 QbD process development paradigm (Adapted from CMC Biotech Working Group^[4])

be given to some aspects than others for a specific product. Tools for developing a robust QTPP are discussed in literature. Of note are two white papers concerning the use of QbD for development of monoclonal antibodies and vaccines.^[4,5]

Product and Process Design

Critical Quality Attributes

The identification of CQAs follows immediately after the QTPP is developed. This allows for the evaluation and control of product characteristics that have impact on quality, safety and efficacy. A CQA is defined as “a physical, chemical, biological, or microbiological property or characteristic that should be within an appropriate limit, range, or distribution to ensure the desired product quality.”^[2] CQAs collectively indicate whether the manufacturing process delivers product that meets its QTPP. The identification of CQAs is usually accomplished through a criticality assessment that evaluates the risk associated with each attribute, including the severity (consequences to the patient), probability (likelihood of occurrence) and detectability of non-conformance of the CQA. Both prior product knowledge and process capability are useful sources of information for such an evaluation. The former includes cumulative laboratory, non-clinical, and clinical experience related to the quality attribute under evaluation, as well as data from molecules in the same class and published literature. The latter consists of data from process development studies and relevant manufacturing

experience from the same or related products. Both product knowledge and process capability serve as the basis for establishing the acceptable range for a CQA.

Since changes in CQAs might have a significant impact on product safety and efficacy, it is critical to establish the relationships between CQAs and clinical performance, and to use this knowledge to define acceptable ranges for CQAs. This knowledge provides a foundation for developing robust control strategies for the manufacturing process. However, it can be difficult to link a particular quality attribute to clinical performance (safety and efficacy).

In the literature, various models have been proposed to understand the relationships between CQAs and product safety and efficacy. For example, for process-related impurities, an impurity safety factor (ISF) is used to link to the toxicity of an impurity to the maximum acceptable level in the product through the following function:^[6]

$$\text{ISF} = \text{LD}_{50}/r$$

where LD_{50} is the amount of an impurity that results in lethality in 50% of animals tested, and r is the maximum amount of an impurity in the final product dose. The higher the ISF, the lower the safety risk caused by the impurity is. If a lower limit on the ISF is available (for example, from regulatory guidelines), it can be translated into a bound on the maximum amount of impurity in a final product dose.

Another example by Yang^[7] describes a method that provides a functional relationship between three correlated CQAs of a monoclonal antibody and a surrogate efficacy marker, namely, area under the drug concentration curve (AUC). Such a linkage allows for the assessment of the impact of changes in these CQAs on the product efficacy, and also allows for the establishment of clinically relevant joint acceptance ranges for the CQAs.

Process Development

After the CQAs are defined, the focus is shifted to the development of a manufacturing process that produces product meeting its QTPP. At this stage of development, studies are carried out, using multivariate design of experiment (DOE) strategies, to evaluate the effects of process variables and their interactions on process performance. Knowledge gleaned from the results of these studies, perhaps combined with platform knowledge and data from other molecules in the same class, will be used to define critical process parameters (CPPs) through a risk assessment. The next step is to optimize the process based on the CPPs identified from the risk assessment. This experimentation also gives rise to a “design space”, which will be defined later. The above sequence of activities is repeated for each unit operation, establishing a design space for the CPPs in each.

Process Control

The implementation of control strategies enables a manufacturing process to consistently deliver quality product. QbD principles call for using a risk-based approach to develop control strategies, aimed at keeping the manufacturing risks at or below acceptable levels. Knowledge of CQAs and the impact of CPPs and other input materials on these CQAs enables manufacturers to avoid unnecessary testing as a means to demonstrate product quality. In essence, the level of control of each quality attribute should reflect the criticality of the attribute. Effective control strategies integrate a number of elements including input material controls, procedural controls, process parameter controls, in-process testing, specification testing, characterization/comparability testing and process monitoring, as appropriate.

DESIGN SPACE

Design space is a key concept in the implementation of QbD. According to ICH Q8 (R2) (2006), a design space is “[t]he multidimensional combination and interaction of input variables (e.g., material attributes) and process parameters that have been demonstrated to provide assurance of quality.” For example, a design space for a cell culture system may have ranges for temperature, pH, feed volume, and culture duration that ensure quality product. Design space is intimately related to quality risk management (QRM) principles. By linking manufacturing variations with the variability of CQAs, it sets the stage for developing effective manufacturing controls. A design space also has regulatory implications for post approval changes as “[w]orking within the design space is not considered as a change. Movement out of the design space is considered to be a change and would normally initiate a regulatory post-approval change process”.^[2] Thus, a well-developed design space may enable a manufacturer to continuously improve the manufacturing process by adapting to novel technologies without incurring additional risk and creating more regulatory hurdles. Most recently, the concept of design space has also been used in analytical method development, which will be discussed in a later section.

STATISTICAL METHODS FOR DESIGN SPACE

Typically, statistical design of experiments (DOE) concepts are used to gain experimental efficiency in obtaining the necessary information regarding the effects of process parameters and input material attributes on the CQAs in order to establish a design space. These experiments are more effective and efficient than “one-factor-at-a-time” (OFAT) studies. Note that not all the process parameters

and material attributes have a significant impact on CQAs. Prior to the characterization studies, a risk analysis is performed to select experimental factors that are deemed to have high or medium impact on CQAs. Knowledge gained from these studies, coupled with other historical data and manufacturing experience, serves as the basis for establishing a design space, product specifications, and manufacturing control strategies.

Several statistical methods have been proposed to determine design space through multivariate regression analysis. Of note are two traditional approaches: overlapping mean response surfaces and the composite desirability function. Using these approaches, a design space is determined to be either a multivariate region in which the mean response values of CQAs are within specifications, or a region in which the composite desirability function (a measure of how well a combination of factor settings optimize the response) exceeds a pre-specified threshold. As pointed out by Peterson,^[8] these traditional methods do not take into account correlations among CQAs, nor do they account for variability in the model prediction. An appropriately constructed design space needs to account for measurement uncertainties, uncertainty about the parameters of the statistical models, and correlations among the measurements, in order to provide high assurance of product quality. In recent years, significant advances have been made in developing design spaces using Bayesian multivariate analysis techniques^[8–17] and further statistical opportunities for design space development still exist. For example, so far the concept of design space is by and large applied to input materials and process parameters. In addition, a design space is usually developed based on experiments and data from small-scale processes. How to update such design spaces, based on data from pilot and full-scale data, remains to be further researched. It will also be of great benefit to bring these statistical methods into common practice through software development.^[18]

Overlapping Mean Response Surfaces

Let $\mathbf{Y} = (Y_1, \dots, Y_p)'$ be a $p \times 1$ vector of measures of p CQAs, A the set of joint acceptable ranges of the CQAs, and $\mathbf{x}$ a $k \times 1$ vector of process parameters and other controllable inputs, such as material attributes. Suppose that the relationship between $\mathbf{Y}$ and $\mathbf{x}$ can be characterized through the model:

$$\mathbf{Y} = \mathbf{f}(\mathbf{x}; \boldsymbol{\theta}) + \boldsymbol{\varepsilon}$$

where $\mathbf{f}(\mathbf{x}; \boldsymbol{\theta})$ is a mathematical function, $\boldsymbol{\theta}$ model parameters, and $\boldsymbol{\varepsilon}$ measurement errors.

Let $\hat{\boldsymbol{\theta}}$ be the vector of estimates of the model parameters. Therefore, the estimate of expected mean values at $\mathbf{x}$ are given by $\hat{E}[\mathbf{Y}|\mathbf{x}] = \mathbf{f}(\mathbf{x}; \hat{\boldsymbol{\theta}})$. The design space based on the overlapping mean approach is defined as

$$\{\mathbf{x} : \hat{E}[\mathbf{Y}|\mathbf{x}] \in A\}.$$

Consider an example regarding the performance of a liquid chromatography method.^[9,10] Data were collected from a Box-Behnken experiment, which has three factors, $\mathbf{x} = (x_1, x_2, x_3) = (\% \text{ isopropyl, temperature, pH})$, and four responses, $\mathbf{Y} = (y_1, y_2, y_3, y_4) = (\text{resolution, run time, signal to noise ratio, tailing})$. The aim of the experiment was to determine the design space of the assay parameters $\mathbf{x}$ that allow for high probabilities for the responses to meet specifications. For this assay, the acceptance region A for the responses is given as

$$A = \{\mathbf{y} : y_1 \geq 1.8, y_2 \leq 15, y_3 \geq 300, 0.75 \leq y_4 \leq 0.85\}.$$

LeBlond^[19] fit the data using a simple regression model:

$$\mathbf{Y} = \mathbf{z}(\mathbf{x})\boldsymbol{\theta} + \boldsymbol{\varepsilon}$$

where

$$\mathbf{z}(\mathbf{x}) = (1, x_1, x_2, x_3, x_1^2, x_2^2, x_3^2, x_1x_2),$$

$$\boldsymbol{\theta} = \begin{pmatrix} \theta_0^{(1)} & \dots & \theta_0^{(4)} \\ \vdots & \ddots & \vdots \\ \theta_7^{(1)} & \dots & \theta_7^{(4)} \end{pmatrix},$$

and $\boldsymbol{\varepsilon}$ is normally distributed with mean 0 and covariance matrix Σ . As depicted in Fig. 2, the design space for temperature and % isopropyl alcohol with pH being set at the middle level 0.175 is the area between the two contours, $y_3 = 300$ and $y_4 = 0.85$, where the condition $\hat{E}[\mathbf{Y}|\mathbf{x}] \in A$ is met.

Fig. 2 Design space determined as the “sweet spot” of settings for two CPPs in which the mean responses for two CQAs meet their respective acceptance criteria (adapted from LeBlond^[19])

As noted by Peterson,^[9] there are several serious drawbacks of this approach. First, the method does not account for uncertainties in the model parameter estimates. Second, it ignores potential correlations among the responses. Third, it does not quantify the level of assurance for meeting specifications when the parameters are inside the design space.

Bayesian Approach

Definition of Bayesian Design Space

As an alternative approach, and to address the deficiencies of the overlapping mean contours and desirability function methods, Peterson^[8] suggested a Bayesian approach to establishing a design space, and an application of the method was demonstrated by Stockdale and Cheng^[14] through two case studies. A Bayesian design space and various extensions were also explored by Lebrun (2012). In general terms, a Bayesian design space is defined as

$$\{\mathbf{x} : \Pr[\mathbf{Y} \in A | \mathbf{x}, \text{data}] \geq R\} \quad (1)$$

where $\mathbf{Y}$, A , and $\mathbf{x}$ are defined as before, “Pr” stands for posterior predictive probability, *data* is the data set from a controlled experiment, which includes measured values of the CQA(s) and various settings of the process parameters, and R is a pre-selected level of reliability that must be met.

Because the posterior predictive probability takes into account the uncertainty in the model parameters and correlation among the response variables, it overcomes the drawbacks of the overlapping mean response surface method. In addition, the Bayesian method can be easily extended to accommodate many different types of experiments such as split-plot^[13] as well as experiments involving mixed effects.^[16] The Bayesian design space can be determined by estimating the probability $\Pr[\mathbf{Y} \in A | \mathbf{x}, \text{data}]$ over a grid of $\mathbf{x}$ values. The posterior predictive probability can be estimated either through a closed-form solution or by Markov Chain Monte Carlo (MCMC) simulations. The concept of a Bayesian design space is illustrated in Fig. 3 for the liquid chromatography method example described earlier.

Regression Model

Several regression models can be used to describe the measured responses of the CQAs ($\mathbf{Y}$). For example, the following model was used by Peterson^[8] and Stockdale and Cheng:^[14]

$$\mathbf{Y} = \mathbf{B}\mathbf{z}(\mathbf{x}) + \mathbf{e} \quad (2)$$

Where $\mathbf{B}$ is a $p \times q$ matrix of regression coefficients, $\mathbf{z}(\mathbf{x})$ is a $q \times 1$ vector function of $\mathbf{x}$, and $\mathbf{e}$ is a $p \times 1$

Fig. 3 Design space (DS) based on Bayesian predictive modeling that links input process parameters x and material attribute z with CQAs Y . The DS is determined such that there is a high probability that the CQAs jointly meet their acceptance criteria when the process parameters and material attributes are within the DS

vector of measurement errors having a multivariate normal distribution with mean $\mathbf{0}$ and covariance-variance matrix Σ .

It is assumed that $\mathbf{z}(\mathbf{x})$ is the same for each CQA though the method described in this section can be extended to the seemingly unrelated regressions (SUR) model (Peterson, 2006), in which each response Y_i ($i = 1, \dots, p$) has a different function $\mathbf{z}_i(\mathbf{x})$. Under such circumstances, the SUR model provides greater flexibility and accuracy in modeling the CQAs (Peterson, 2007). A SUR model takes the form:

$$Y_j = \mathbf{z}_j(\mathbf{x})'\beta_j + e_j, \quad j = 1, \dots, p.$$

The SUR model includes the standard multivariate regression model as a special case where $\mathbf{z}_j(\mathbf{x}) = \mathbf{z}(\mathbf{x})$. A design space based on the SUR model and posterior predictive probability can be similarly obtained.^[20]

Prior Information

Use of prior information (regarding process/method parameters, CQAs, etc.) is a critical step in Bayesian inference. Peterson^[8] discussed various ways in which prior information can be elicited for a design space model. For example, an informative prior distribution may be established from experiments done at the pilot scale, with the intention of being used for developing a design space for commercial scale manufacturing. However, oftentimes data from pilot scale experiments alone may not be sufficient for constructing informative priors. Peterson (2008) discussed three additional sources of information that can be potentially used for specifying informative prior distributions. Please refer to Peterson^[8] for detail.

Posterior Predictive Probability and Design Space

Let $\mathbf{Y}_{obs} = (\mathbf{Y}_1, \dots, \mathbf{Y}_n)'$ be an $n \times p$ matrix consisting of n observations of the $1 \times p$ response vector $\mathbf{Y}$.

Let $\mathbf{Z}_{\text{exp}} = (\mathbf{Z}_1, \dots, \mathbf{Z}_n)'$ be an $n \times q$ matrix with $\mathbf{Z}_i = \mathbf{z}(\mathbf{x}_i)$, $i = 1, \dots, n$, and let $\mathbf{x}_i$ be the i^{th} condition of the controllable input variables and process parameters. Assuming that a non-informative prior is used to describe the parameters $(\mathbf{B}, \Sigma)$:

$$p(\mathbf{B}, \Sigma) \propto |\Sigma|^{-(p+1)/2}. \quad (3)$$

It is well known^[21] that the posterior predictive distribution of a future observation $\tilde{\mathbf{Y}}$ in this case is a multivariate-t with degrees of freedom $\nu = n - p - q + 1$:

$$\tilde{\mathbf{Y}} | \mathbf{x}, \text{data} \sim t_{\nu}(\hat{\mathbf{B}}\mathbf{z}(\mathbf{x}), \mathbf{H}) \quad (4)$$

where

$$\mathbf{H} = [1 + \mathbf{z}(\mathbf{x})' \mathbf{D}^{-1} \mathbf{z}(\mathbf{x})] \hat{\Sigma},$$

$$\mathbf{D} = \sum_{i=1}^n \mathbf{Z}_i \mathbf{Z}_i',$$

and $\hat{\mathbf{B}}$ and $\hat{\Sigma}$ are the least squares estimates of $\mathbf{B}$ and Σ given by

$$\hat{\mathbf{B}} = (\mathbf{Z}_{\text{exp}}' \mathbf{Z}_{\text{exp}})^{-1} \mathbf{Z}_{\text{exp}}' \mathbf{Y}_{\text{obs}}$$

$$\hat{\Sigma} = [\mathbf{Y}_{\text{obs}} - (\hat{\mathbf{B}}\mathbf{Z})'] [\mathbf{Y}_{\text{obs}} - (\hat{\mathbf{B}}\mathbf{Z})'] / \nu \text{ with } \nu = n - p - q + 1.$$

Because the posterior predictive distribution is a multivariate t -distribution, it can be simulated as follows:^[20]

1. Draw $\mathbf{W}$ from the multivariate normal distribution $N(\mathbf{0}, \mathbf{H})$;
2. Draw $\mathbf{U}$ from the chi-square distribution χ_{ν}^2 ;
3. Calculate $Y_j = \sqrt{\nu} W_j / \sqrt{\mathbf{U}} + \hat{\mu}_j$, for $j = 1, \dots, p$, where Y_j , W_j , and $\hat{\mu}_j$ are the j^{th} elements of $\mathbf{Y}$, $\mathbf{W}$, and $\hat{\mathbf{B}}\mathbf{z}(\mathbf{x})$, respectively.

As suggested by Peterson (2009), the posterior predictive probability can be approximated using Monte Carlo simulation:

$$p(\mathbf{x}) = \Pr[\mathbf{Y} \in A | \mathbf{x}, \text{data}]$$

$$\approx \frac{1}{N} \sum_{s=1}^N I(\mathbf{Y}^{(s)} \in A)$$

where $\mathbf{Y}^{(s)}$, $s = 1, \dots, N$, are independent random multivariate-t variables simulated from the above-mentioned procedure, and $I(\cdot)$ is an indicator function taking values of either 0 or 1. The design space defined in (1) can be obtained by estimating the posterior predictive probability $p(\mathbf{x})$ over a grid of $\mathbf{x}$ values and comparing it to the reliability threshold R .

Alternatively, as discussed previously, informative prior distributions may be used in the derivation of the posterior predictive probability. For example, one may use conjugate prior distributions for $p(\mathbf{B} | \Sigma)$ and $p(\Sigma)$:^[16]

$$\mathbf{B} | \Sigma \sim N_{p \times q}(\mathbf{B}_0, \Sigma, \Sigma_0)$$

$$\Sigma \sim W_1^{-1}(\Omega, \nu_0)$$

Where $\mathbf{B}_0$ is the mean vector and Σ and Σ_0 are the covariance matrices of the columns and rows of $\mathbf{B}$, respectively; Σ follows an inverse-Wishart distribution with Ω being an *a priori* response scale matrix, and ν_0 the degrees of freedom.

It was shown by Lebrun (2012) that the posterior predictive probability in this case is also a multivariate t -distribution. Thus, using the Monte Carlo simulation procedure previously described, the Bayesian design space can be constructed.

Example

For the liquid chromatography method example previously discussed, LeBlond (2014) presented a design space calculation based on method (2). The design space is $\{\mathbf{x} : \Pr[\mathbf{Y} \in A | \mathbf{x}, \text{data}] \geq 0.99\}$. To calculate the posterior predictive probability, minimally informative priors b_0 , b_3 , and $b_6 \sim N(0, 0.0001)$, b_1 and $b_2 \sim N(0, 0.001)$, and b_4 , b_5 , and $b_7 \sim N(0, 0.01)$ are used for the eight regression coefficients in model (2), based on examining the results of a frequentist analysis of the data, and a scalar inverse Wishart prior is used for the variance-covariance matrix.^[18] The prior for the variance-covariance matrix is assigned based on a method suggested by Gelman and Hill.^[22] To begin, the variance-covariance matrix is first expressed as

$$\Sigma = \text{Diag}(\xi) \mathbf{Q} \text{Diag}(\xi),$$

where $\text{Diag}(\xi)$ is a diagonal matrix with diagonal elements $\xi = (\xi_1, \xi_2, \xi_3, \xi_4)$ and $\mathbf{Q}$ is a correlation matrix given by

$$\mathbf{Q} = \begin{pmatrix} 1 & \rho_{12} & \rho_{13} & \rho_{14} \\ \rho_{21} & 1 & \rho_{23} & \rho_{24} \\ \rho_{31} & \rho_{32} & 1 & \rho_{34} \\ \rho_{41} & \rho_{42} & \rho_{43} & 1 \end{pmatrix}.$$

The parameters $\xi = (\xi_1, \xi_2, \xi_3, \xi_4)$ are chosen as $U(0, S_i)$ ($i = 1, \dots, 4$) with S_i being the frequentist estimate of the 99% upper confidence limit, of the square root of the i^{th} diagonal element of Σ , and $\mathbf{Q}$ is distributed according to $IW(\mathbf{I}, 5)$, where $\mathbf{I}$ is the 4×4 identity matrix. This representation of the priors has the advantage of using separate priors for the variances and the correlation coefficients. Using MCMC methods, the posterior predictive probability for a future CQA response is estimated and the resulting design space is depicted, along with the overlapping mean contours for comparison, in Fig. 4.

Fig. 4 Bayesian design space in which the predictive posterior probability for the responses to meet the acceptance criteria exceeds 99%. Also shown are overlapping mean contours from a regression model (adapted from LeBlond^[18])

Such a design space provides over 99% confidence that movement within the design space has no impact on the assay's ability to meet its specification.

CONTINUED PROCESS VERIFICATION

Continued process verification (CPV) is the next step in the lifecycle of the product/process, following successful process performance qualification. The goal of CPV is to demonstrate that the process continues to consistently produce product that meets its quality standard. In addition, CPV provides opportunities to either confirm that the control strategies are appropriate or identify other sources of variations that might require modification of specifications, in-process controls, or process improvements. Central to the fulfilment of these objectives is a system or systems for detecting unplanned departures from the process as designed, through monitoring and review of data collected from post approval batches. It is also critical that the data collection and analysis is performed in accordance with cGMP requirements, and that proper corrective and preventive action(s) be taken when deviations are detected. The data should include relevant product quality attributes and process parameters, incoming materials or components measurements, in-process tests. The use of statistical tools such as statistical process control (SPC) and process analytical technologies may potentially provide real-time process monitoring.

Traditionally, univariate SPC charts such as Shewhart, CUSUM, and EWMA charts have been used to monitor process performance over time.^[23] However, a major drawback of these univariate methods is that they do not account

for interdependence among the variables being monitored. As large and complex data sets including process parameters, quality attributes, properties of raw materials, and environmental factors of manufacturing areas are likely to include many and complex correlations, using independent univariate control charts may fail to identify out of control observations. The issue was illustrated by Kourti and MacGregor,^[24] as reproduced in Fig. 5. The process data of two quality attributes (y_1, y_2) are plotted, with the confidence region for (y_1, y_2) indicated by the ellipse and the respective univariate control limits by the dotted lines. It is clear that the out of control batch indicated by "*" would have been misidentified if only the univariate controls charts were used.

Multivariate analysis techniques such as principal components analysis (PCA) and partial least squares (PLS) are effective statistical tools dealing with interdependence among variables. Through reducing the dimensionality of multivariate data, these methods make monitoring of complex data manageable. They have been often used by many companies for monitoring the performance of manufacturing processes and analytical methods, qualifying batches of raw materials, demonstrating comparability pre- and post-changes.

In the following, we use an example from the a-Mab CMC case study^[4] to illustrate how to verify a scale-down model (2L) that was used to predict large scale (15, 000) production bioreactor performance, based on commercial scale batch data. This can be used as a CPV effort. Both scales use the same cell host, expression system and a similar cell culture process, and are characterized through thirteen quality attributes. A PCA was performed, and the results indicated that 99.4% of the variability in the data set was explained by the first five principal components. To demonstrate the comparability between the two scales, a 95% confidence ellipsoid for the five principal components was constructed based on the production scale data set and is shown in Fig. 6. The corresponding principal

Fig. 5 Performance of multivariate control chart versus univariate control charts (adapted from Kourti and MacGregor^[24])

Fig. 6 Scale comparison based on PCA with black and blue triangles corresponding to small and production scales, respectively (Adopted from CMC Biotech Working Group^[4])

components of the small-scale batches are plotted and shown to be within the confidence ellipsoid, indicating comparable performance between the two scales.

QBD APPROACH TO ANALYTICAL METHOD DEVELOPMENT

Critical enablers to ensuring manufacturing consistency, analytical methods play a central role in biopharmaceutical research and development. Traditionally analytical method was developed and validated in accordance with regulatory requirements such as ICH Q2, Validation of Analytical Procedures: Methodology. For example, method validation consists of a series of experiments intended to demonstrate that an analytical method meets pre-specified acceptance criteria for accuracy, precision, linearity and etc. In recent years, there has been a shift within the industry from a compliance-driven analytical method development paradigm towards a lifecycle approach rooted in QbD. For example, Borman et al.^[25] suggested using a QbD approach for analytical methods that includes risk assessment, robustness and ruggedness testing, and assessment of method variability compared with the specification limits to determine whether the method is fit for its intended purpose. Viewing an analytical procedure as a process and data as its product, Nethercote et al.^[26] argued that QbD concepts for manufacturing process development can be applied to analytical methods, including the concepts of lifecycle validation. Analytical QbD, aligning understanding of analytical method variability with its intended use, is further explored and described in several publications.^[25,27,28] In recent years, analytical QbD also has attracted much attention from USP and FDA.

The culmination of these efforts is the proposal that the three stages of process validation be applied to analytical method validation (Nethercote and Ermer, 2012; Martin et al. 2014), as depicted in Fig. 7.

The starting point of this approach is to define an analytical target profile (ATP), which describes the quality of the data that the method is required to produce. The concept of ATP was first proposed by the EFPIA/PhRMA working group^[29] and adopted by the USP Validation and Verification Expert Panel.^[28] The ATP is constructed based on understanding the measurement uncertainty of the method and measurand, and the required level of assurance regarding the reportable results. Several considerations need to be taken into account when defining the ATP.^[30] They include (1) the range over which the analytical method is expected to reliably quantify the amount or potency of analyte; (2) the total acceptable uncertainty or error, which measures the closeness between the reportable value and the true value, and which is expressed as the sum of systematic and random errors; and (3) a description of the analyte to be tested, including the sample or matrix in which it will be tested. The ATP is used to guide method development, performance qualification, and continued verification throughout the lifecycle of the method. It is critical to link the traditional assay characteristics such as accuracy and precision to the ATP. Such a link enables the definition of acceptance criteria for these performance parameters in the method performance qualification study.

After the ATP is defined, the analyst proceeds to Stage 1 Method Design, in which the analyst selects an appropriate analytical technique and develops a draft method that may meet the requirements defined in the ATP. As understanding sources of variability is one of the primary focuses at this stage, risk assessment tools such as Ishikawa or fishbone diagrams, FEMA, etc., can be used to gain understanding of variables that may have an impact on the method performance, and help prioritize experimentation.^[28] DOEs are carried out to determine ranges of key method parameters in which the ATP may be met. Stage 2 Method Qualification is intended to confirm that the method is fit for its intended purpose through formal studies. This stage

Fig. 7 Life cycle approach to analytical procedure validation

involves the collection of data from performing the analytical procedure under routine operating conditions, and demonstration that the data meet acceptance criteria in the ATP. In addition, knowledge of the analytical procedure gleaned from the method qualification studies can be used to develop control strategies. The objective of Stage 3 Continued Procedure Performance Verification is to provide assurance that the method remains in a state of control during routine use. This involves routine monitoring to confirm the analytical procedure's performance, and also performance verification after any changes made to the method. Statistical process control charts can be used to capture any special-cause variation.

CONCLUSIONS

Since the launch of the FDA initiative "Pharmaceutical cGMPs for the 21st Century" in 2002, there has been a significant progress in developing QbD approaches for biopharmaceutical products. Biopharmaceutical product and process development, due to the high level of complexity, would benefit from greater use of available data and tools for risk assessment and development of design space and control strategies. How effectively to synthesize information from various sources, quantify manufacturing variability and risk, identify CQAs, determine design space, and devise effective control strategies is the key to the implementing a QbD approach. All of these rely on statistical methodologies for experimental design and data analysis. Statistical advances, particularly in the area of Bayesian modeling and computation have brought about new opportunities for applying QbD principles in biopharmaceutical development.

ACKNOWLEDGEMENT

The author would like to thank Ms. Katherine Giacoletti and Dr. Lorin Roskos for their helpful review of the article.

Abstract

Randomization plays an important role in the conduct of clinical trials. This entry discusses several models and methods of clinical trial randomization and reviews the statistical effects randomization has on clinical trials as well as examples of when randomization is not feasible.

INTRODUCTION

Randomization plays an important role in the conduct of clinical trials. Randomization not only generates comparable groups of patients who constitute representative samples from the intended patient population but also enable valid statistical tests for clinical evaluation of the study drug. Randomization in clinical trials involves random recruitment of the patients from the targeted population and random assignment of patients to the treatments. For a valid statistical assessment of the efficacy and safety of a study drug, it is important that a representative sample of qualified patients be randomly selected from the targeted patient population. A qualified patient is referred to as a patient who meets the inclusion and exclusion criteria and has signed the informed consent form. Randomization avoids subjective selection bias for the integrity and the scientific and/or statistical validity of the intended clinical trials. Patients participating in the clinical trials are randomly assigned to one of the treatments under study which avoids subjective assignment of treatments. When there are heterogeneity in demographics and/or patient characteristics, randomization with blocking and/or stratification is helpful in removing the potential bias that might occur due to the differences in demographics and/or patient characteristics. Under randomization, statistical inference can be drawn under some probability distribution assumption of the intended patient population. The probability distribution assumption depends on the method of randomization under a randomization (population) model. A study without randomization will result in the violation of the probability distribution assumption; consequently, no accurate and reliable statistical inference on the study drug can be drawn.

RANDOMIZATION MODELS

In practice, the selection of patients may be performed under different principles of randomization. Lachin^[1] provided a comprehensive summarization of randomization basis for statistical tests under various models which are summarized in this section.

Population Model

The concept for selecting a representative sample from a patient population by some random procedures for obtaining statistical inference by which clinicians can draw conclusions regarding the patient population is called the *population model*.^[1,2] Under the assumption of a homogeneous population, the clinical responses of all patients in the trial are independent and have the same distribution. Lachin^[1] pointed out that the significance level and power will not be affected by random assignment of patients to the treatments as long as the patients in the trial represents a random sample from the homogeneous population. If we split a random sample into two subsamples, statistical inferential procedures are still valid even if the first half patients are assigned to the study drug and the other half are assigned to a placebo.

Invoked Population Model

When planning a clinical trial, we usually select investigators first and then recruit/enroll qualified patients at each selected investigator's site sequentially. As a result, neither the selection of investigators (or study centers) nor the recruitment of patients is random. However, patients who enter a trial are assigned to treatment groups at random. In practice, the collected clinical data

are usually analyzed as if they were obtained under the assumption that the sample is randomly selected from a homogeneous patient population. Lachin^[1] referred to this process as the *invoked population* model because the population model is invoked as the basis for statistical analysis as if a formal sampling procedure were actually performed. In current practice, the invoked population model is commonly employed in data analysis for most clinical trials. However, it should be noted that the invoked population model is based on the assumption that is inherently instable.

Randomization Model

For current practice, although the process for study site selection and for patient recruitment are not random, the assignment of treatments to patients is performed based on some random mechanism. Thus, treatment comparisons can be made based on the so-called randomization or permutation tests. We will refer this process as the *randomization model*. Because the statistical procedures based on the concept of permutation require the enumeration of all possible permutations, it is feasible only for small samples. When the sample size increases, the probability distribution derived under permutation will approach to a normal distribution according to the Central Limit Theorem. Lachin^[3] indicated that the probability distributions for the family of linear rank statistics for large samples are equivalent to those of the tests obtained under the assumption of the population model. As a result, if patients are randomly assigned to the treatments, statistical tests for evaluation of treatments should be based on permutation tests because the exact *p*-value can be easily calculated for small samples. For large samples, the data can be analyzed by the methods derived under the population model as if the patients were randomly selected from a homogeneous population.

RANDOMIZATION METHODS

In general, randomization methods for treatment assignment can be classified into three types according to the restriction of the randomization and the change in probability for randomization with respect to the previous treatment assignments. These randomization methods include the complete randomization, the permuted-block randomization, and the adaptive randomization. In what follows, we will describe these randomization methods and compare their relative merits and limitations whenever possible.

Complete Randomization

Simple randomization or complete randomization is the procedure in which no restrictions are enforced on the

nature of randomization sequence except for the number of patients required for achieving the desired statistical power and the ratio of patient allocation between treatments. For a clinical trial comparing a study drug with a placebo, the method of simple randomization is referred to as a completely binomial design^[4] or a simply complete randomization^[3] if it has the following properties: (i) the chance that a patient receives either the test drug or the placebo is 50%, and (ii) randomization of assignments are performed independently for each patient. The randomization codes based on the method of complete randomization can be generated either by random numbers^[5] or by some statistical computing software such as SAS. However, it should be realized that a computer cannot generate *true* random numbers, but pseudo random numbers, because only a fixed number of different long series of almost unpredictable permuted numbers is generated. Therefore, Lehmann^[2] recommended that a run test be performed to verify the randomness of the generated randomization codes.

Permuted-Block Randomization

One of the major disadvantages of the simple randomization is that treatment imbalance may occur periodically. One resolution to this major disadvantage of simple randomization is to force balance of the number of patients assignment to each treatment periodically. In other words, we first divide the whole series of patients who are to enroll into the trial into blocks with appropriate (typically equal) blocking sizes. We then randomize the patients within each block to ensure that an equal number of patients will be assigned to each of the two treatment groups. For example, a blocking size of two guarantees that each treatment group will be assigned one patient for the first two patients enrolled into the study. A blocking size of four indicates that two patients of the first four patients who enter the study will be randomly assigned to each of the two treatment groups. This method of randomization is known as the *permuted-block randomization*. Permuted-block randomization is probably the most frequently employed method for the assignment of patients to treatments in clinical trials.

Permuted-block randomization is in fact a stratified randomization. Therefore, a stratified analysis should be performed with blocks as strata to properly control the overall type I error rate and, hence, to provide the optimal power for detection of a possible treatment effect. In practice, the block effect is usually ignored when performing data analysis. Matts and Lachin^[6] showed that the test statistic ignoring the block is equal to 1 minus the intrablock correlation coefficient times the test statistic which takes the block into account. Because the patients within the same block are usually more homogeneous than those between blocks, the intrablock correlation coefficient is often positive. As a result, the tests which ignore block

will produce more conservative results. However, because most clinical trials are multicenter studies with a moderate block size, it is not clear from their discussion whether a saturated model with factors treatment, center, and block and their corresponding two-factor and three-factor interactions should be included in the analysis of variance. It is not clear whether the Mantel–Haenszel test and linear rank statistics based on permutation model are adequate for a complete combination of all levels of all strata with a very small number of patients in each stratum. In addition, when block size is large, there is a high possibility that a moderate number of patients fall in the last block at which the randomization codes are not entirely used up. If the trial is also stratified according to some covariates, the number of patients in such incomplete block will become quite sizable. Therefore, a stratified analysis will be quite complicated because of these incomplete blocks from all strata and the possible presence of intrablock correlation coefficient.

A practical issue related to permuted-block randomization is the choice of block size. A small blocking size, such as two, may prevent treatment imbalance; however, it may result in a high intrablock correlation coefficient and, thus, a large loss of power. Note that a smaller block size leads to a higher probability of guessing the treatment code right, which may decrease the reliability of blinding and, consequently, the integrity of the study.

Adaptive Randomization

In addition to the permuted-block randomization, it is also of interest to adjust the probability of assignment of patients to treatments during the study. This type of randomization is called the *adaptive randomization* because the probability for the assignment of current patient is adjusted based on the assignment of previous patients. Unlike other randomization methods described above, the randomization codes based on the method of adaptive randomization cannot be prepared before the conduct of the study because the randomization process is actually performed at the time when a patient is enrolled into the study and that the adaptive randomization requires the information of previous randomized patients. In clinical trials, the method of adaptive randomization is often applied with respect to treatment, covariate, or clinical response. Therefore, the adaptive randomization is also known as the treatment adaptive randomization, the covariate adaptive randomization, or the response adaptive randomization. Treatment adaptive randomization has been discussed in literature by many researchers (see, e.g., Efron,^[7] Wei,^[8,9] and Wei and Lachin^[10]). The response adaptive randomization has also received much attention since introduced by Zelen^[11] (see, e.g., Wei et al.^[12] and Rosenburger and Lachin^[13]). More details regarding the covariate adaptive randomization can be found in Taves,^[14] Pocock,^[5] and Spilker.^[15]

EFFECT OF MIXED-UP RANDOMIZATION CODES

A problem that commonly encountered during the conduct of a clinical trial is that a proportion of treatment codes are mixed up in randomization schedules. Mixing up treatment codes can distort the statistical analysis based on the population or randomization model. In what follows, we introduce a method proposed by Chow and Shao^[16] to quantitatively study the effect of mixed-up treatment randomization codes.

Consider a two-group parallel design for comparing a test drug and a control (placebo), where n_1 patients are randomly assigned to the treatment group and n_2 patients are randomly assigned to the control group. When randomization is properly applied, the population model holds and responses from patients are normally distributed. Consider the simple case where two patient populations (treatment and control) have the same variance σ^2 . Let μ_1 and μ_2 be the population means for the treatment and the control, respectively. The null hypothesis that $\mu_1 = \mu_2$ (i.e., there is no treatment effect) is rejected at the 5% level of significance if

$$T = \frac{|\bar{x}_1 - \bar{x}_2|}{\hat{\sigma} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} > t_{0.975; n_1 + n_2 - 2} \quad (1)$$

where

$$\hat{\sigma}^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$$

$\bar{x}_1$ and s_1^2 are the sample mean and variance of responses from patients in the treatment group, respectively; $\bar{x}_2$ and s_2^2 are the sample mean and variance of responses from patients in the control group, respectively; and $t_{0.975; n_1 + n_2 - 2}$ is the 97.5th percentile of the t distribution with $n_1 + n_2 - 2$ degrees of freedom. The power of the test defined by Eq. 1, i.e., the probability of correctly detecting a treatment difference when $\mu_1 \neq \mu_2$, is

$$\begin{aligned} p(\theta) &= P(T > t_{0.975; n_1 + n_2 - 2}) \\ &= 1 - \mathcal{T}_{n_1 + n_2 - 2}(t_{0.975; n_1 + n_2 - 2} | \theta) \\ &\quad + \mathcal{T}_{n_1 + n_2 - 2}(-t_{0.975; n_1 + n_2 - 2} | \theta) \end{aligned}$$

where

$$\theta = \frac{\mu_1 - \mu_2}{\sigma \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

and $\mathcal{T}_{n_1 + n_2 - 2}(\cdot | \theta)$ is the noncentral t distribution function with $n_1 + n_2 - 2$ degrees of freedom and the noncentrality

parameter θ . This follows from the fact that under the population model, $\bar{x}_1 - \bar{x}_2$ has the normal distribution with mean $\mu_1 - \mu_2$ and variance $\sigma^2[(1/n_1) + (1/n_2)]$; $(n_1 + n_2 - 2)\hat{\sigma}^2$ has the chi-square distribution with $n_1 + n_2 - 2$ degrees of freedom; and $\bar{x}_1 - \bar{x}_2$ and $\hat{\sigma}^2$ are independent. When $n_1 + n_2$ is large,

$$p(\theta) \approx \Phi(\theta - 1.96) + \Phi(-\theta - 1.96)$$

where Φ is the standard normal distribution function.

Suppose that in each treatment group, patients independently have probability p to mix up their treatment codes. A straightforward calculation shows that the mean of $\bar{x}_1 - \bar{x}_2$ is

$$E(\bar{x}_1 - \bar{x}_2) = (1 - 2p)(\mu_1 - \mu_2)$$

and the variance of $\bar{x}_1 - \bar{x}_2$ is

$$\text{Var}(\bar{x}_1 - \bar{x}_2) = \left[\sigma^2 + p(1-p)(\mu_1 - \mu_2)^2 \right] \left(\frac{1}{n_1} + \frac{1}{n_2} \right)$$

Under the null hypothesis that $\mu_1 = \mu_2$, the distributions of $\bar{x}_1 - \bar{x}_2$ and $\hat{\sigma}^2$ are the same as those in the case of no mixed-up treatment codes; hence, mixing up codes does not have any effect on the significance level of the test defined by Eq. 1. When $\mu_1 \neq \mu_2$ and $p > 0$, $\bar{x}_1 - \bar{x}_2$ is no longer normally distributed but is approximately normal when both n_1 and n_2 are large. Also, $\hat{\sigma}^2$ is a consistent estimator of $\sigma^2 + p(1-p)(\mu_1 - \mu_2)^2$ when $n_i \rightarrow \infty$ for $i = 1, 2$. Thus, the power of the test defined by Eq. 1 is approximately

$$p(\theta_m) = \Phi(\theta_m - 1.96) + \Phi(-\theta_m - 1.96) \quad (2)$$

where

$$\begin{aligned} \theta_m &= \frac{(1-2p)(\mu_1 - \mu_2)}{\sqrt{\left[\sigma^2 + p(1-p)(\mu_1 - \mu_2)^2 \right] \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}} \\ &= \frac{(1-2p)\theta}{\sqrt{1 + \frac{p(1-p)(\mu_1 - \mu_2)^2}{\sigma^2}}} \\ &= \frac{(1-2p)\theta}{\sqrt{1 + p(1-p)\theta^2 \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}} \end{aligned}$$

(assuming that $0 < p < 0.5$). Note that $\theta_m = \theta$ if $p = 0$; that is, there is no mixed-up treatment codes.

The effect of mixed-up treatment codes can be measured by comparing $p(\theta)$ with $p(\theta_m)$. Suppose

that $n_1 = n_2 = 100$, and when there is no mixed-up treatment codes, $p(\theta) = 80\%$, which gives that $|\mu_1 - \mu_2|/\sigma = 0.397$ and $|\theta| = 2.81$. When 5% of treatment codes are mixed up, i.e., $p = 5\%$, $p(\theta_m) = 71.23\%$. When $p = 10\%$, $p(\theta_m) = 60.68\%$. Hence, a small proportion of mixed-up treatment codes may seriously affect the probability of detecting treatment effect when such an effect exists. The effect of mixed-up treatment codes is higher when n_1 and n_2 are not large. Table 1 lists simulation approximations to the values of power of the test defined by Eq. 1 when $n_1 = n_2 = n_0$ is 10, 15, 20, or 30 and $p = 1\%$, 3%, 5%, or 10%. It can be seen that when $n_0 \leq 30$, the actual power is substantially lower than that given by formula 2 with $n_0 = 100$.

When $n_1 = n_2 = n_0$ is large, we may plan ahead to ensure a desired power when the maximum proportion of mixed-up treatment codes is known. Assume that the maximum proportion of mixed-up treatment codes is p and the desired power is 80%, i.e., $|\theta| = 2.81$. Let n_w be the sample size for which the power is equal to 80% when there are 5% of mixed-up treatment codes. Then

$$\frac{(1-2p) \left| \frac{\mu_1 - \mu_2}{\sigma} \right| \sqrt{\frac{n_w}{2}}}{\sqrt{1 + p(1-p) \left| \frac{\mu_1 - \mu_2}{\sigma} \right|^2}} = \left| \frac{\mu_1 - \mu_2}{\sigma} \right| \sqrt{\frac{n_0}{2}}$$

which is the same as

$$(1-2p)^2 n_w = n_0 \left[1 + p(1-p) \left| \frac{\mu_1 - \mu_2}{\sigma} \right|^2 \right] = n_0 + 2p(1-p)\theta^2$$

Therefore,

$$n_w = \frac{n_0}{(1-2p)^2} + \frac{2p(1-p)\theta^2}{(1-2p)^2}$$

will maintain the desired power when the proportion of mixed-up treatment codes is no larger than p . For example, if $p = 5\%$ and 80% power is desired, then $\theta^2 = 2.81^2$ and $n_w = 1.235n_0 + 1.026$. Hence, $n_w = 1.24n_0$; that is, a 24% increase of the sample size will offset a 5% mix-up in randomization schedules.

When n_1 and n_2 are small, it is difficult to estimate a new sample size to ensure a desired power even when the maximum proportion of mixed-up treatment codes is known. A simulation study may be helpful. For example, suppose that $n_1 = n_2 = n_0 = 10$ and $(\mu_1 - \mu_2)/\sigma = 1.26$, which results in a power of 75.84% when $p = 0$ (Table 1). If $p = 5\%$, then the power is 63.59%. According to the results in Table 1, the power is 74.1% when $p = 5\%$ and $\theta = 3.24$. Hence, we need to increase the sample size so that $\theta = 3.24$ in order to ensure a power comparable to the original power 75.84%; that is, the new sample size should be $n_w = 2(3.24/1.26)^2 = 13.22$. Thus, a recommended new sample size is $n_1 = n_2 = 14$.

Table 1 Power of the Two-Sample t Test Approximated by Monte Carlo of Size 10,000

n_0	$(\mu_1 - \mu_2)/\sigma$	θ	p (%)				
			0	1	3	5	10
10	1.26	2.81	0.7584	0.7372	0.6844	0.6359	0.5156

	0.84	3.24	0.8945	0.8791	0.8423	0.8101	0.6963

CONCLUSION

In some situations, deliberate unequal allocation of patients between treatment groups may be desirable. For example, it may be of interest to allocate patients to the treatment and a control in a ratio of 2:1. Such situations include the following: (i) the patient population is small; (ii) previous experience with the study drug is limited; (iii) the response profile of the competitor is well known; and (iv) there are missing values, and the rates of missing depend on the treatment groups.

Randomization is one of the key elements for the success of clinical trials intended to address scientific and/or medical questions. However, it should be noted that in many situations, randomization may not be feasible in clinical research. For example, nonrandomized observational or case-controlled studies are often conducted to study the relationship between smoking and cancer. However, if the randomization is not used for some medical considerations, the Food and Drug Administration (FDA) requires that statistical justification should be provided with respect to how systematic selection bias can be avoided.

Randomized Trials with Clusters: Design and Analysis

Sin-Ho Jung, Ph.D

Department of Biostatistics and Bioinformatics Duke University, Durham,
North Carolina, U.S.A.

Abstract

In clustered data, each cluster consists of multiple subjects, called subunits, and observations are collected from the subjects of each cluster. Since the subjects in each cluster share some common frailties, their outcome data are usually positively correlated. In a randomized study, we can consider one of two randomization strategies. The first strategy, called cluster randomization, is to randomize clusters among treatment arms. In this case, all subjects within each cluster receive the same treatment, so that dependency of the outcome data exists within each treatment arm only and the outcome data among different arms are independent. The second strategy, called subunit randomization, is to randomize the subjects within each cluster between different treatment arms. In this case, subjects within each cluster receive different treatments as randomized, so that dependency of the outcome data exists both within each treatment arm and across different treatment arms. In comparing the mean outcome level among different arms, we have to appropriately account for the dependency in both the sample size calculation and the subsequent statistical analysis. In this chapter, we investigate some estimators of binary response rate and test statistics for comparing the response rates between two arms using these estimators. We consider both cluster and subunit randomization strategies and we assume that the number of subunits is possibly random among clusters.

Keywords: Chi-square statistic; Cluster randomization; Intraclass correlation coefficient; Optimal weight; Subunit randomization; Varying cluster size.

1 INTRODUCTION

Clustered data occur frequently in many fields of application. Examples include the development of tumors in one or more animals of a litter, the presence of retinitis in either or both eyes of an AIDS patient, and community trials for vaccine development. In these examples, litters, AIDS patients, and communities are clusters, and the observations are made from animals, eyes, and community members which are called subunits. For the practical purpose, we often randomize clusters between different treatment arms. In this case, while the clusters are independent, the subunits within each cluster are not. Consequently, the standard test statistics to compare between treatment arms using independent observations are not valid.

In the presence of cluster effect, the application of Pearson chi-square statistic is not valid to compare the response rates among treatment arms. Donner^[1] and Donner and Banting^[2] proposed an adjusted chi-square statistic by assigning an equal weight to each subunit for testing the homogeneity of response rates from such clustered data. Lee and Dubin^[3] and Lee^[4] proposed a weighted estimator which assigns the same weight to each cluster regardless of the number of subunits in each cluster, called cluster size. These two weighting methods are identical if the cluster

size is constant among clusters. Jung and Ahn^[5] introduced an optimal weight estimator that minimizes the variance of the response probability.

Sometimes, we randomize the subunits of each cluster among different treatment arms, which is called subunit randomization. An example arises from a clinical trial conducted to evaluate influence of HL-A (human lymphocyte antigen) on survival of allogeneic grafts (defined as time to rejection of graft) in burned patients^[6]. The donor and recipient were first matched for ABO blood types and then either closely or poorly matched for HL-A antigens. Selected skin grafts (subunits) from at least two unrelated types of donors were applied to each patient (cluster), so that each patient has skin grafts of both close and poor HL-A match. The objective of the study was to discover whether avoiding severe HL-A incompatibility will extend allograft survival time.

In this chapter, we assume that we observe a binary response from each subunit, and propose modified chi-square test statistics accounting for the cluster effect under both cluster randomization and subunit randomization. If the cluster sizes are random, we can consider three different weighting systems to estimate the response probability for each treatment group, (i) equal weights to subunits, (ii) equal weights to clusters, and (iii) optimal weights.

Readers may refer to Donner and Klar^[7] for an excellent review of history, design issues, statistical methods of cluster randomization trials.

2 MODIFIED χ^2 TESTS

We restrict our discussion in this chapter to the comparison of response rates between two arms, but extension to more than two arms is straightforward. Under each of cluster or subunit randomization, we investigate modified χ^2 test accounting for cluster effect by using three different weighting methods. These three test statistics are identical if the cluster size is identical for all clusters.

2.1 Under Cluster Randomization

Suppose that n_k clusters are randomized to arm $k (= 1, 2)$. Let m_{ki} denote the number of subunits for cluster $i (= 1, \dots, n_k)$ in arm k . Under cluster randomization, all subunits on each cluster belong to the same arm. Let y_{kij} denote a binary variable indicating a response ($y_{kij} = 1$) or no response ($y_{kij} = 0$) for subunit $j (= 1, \dots, m_{ki})$ with $P(y_{kij} = 1) = p_k$. We assume that subunits in each cluster are exchangeable with intraclass correlation coefficient $\rho_k = \text{corr}(y_{kij}, y_{kij'})$ for $j \neq j'$. However, units from different clusters are assumed to be independent. Let $y_{ki} = \sum_{j=1}^{m_{ki}} y_{kij}$, $y_k = \sum_{i=1}^{n_k} y_{ki} = \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} y_{kij}$, $M_k = \sum_{i=1}^{n_k} m_{ki}$, $M = M_1 + M_2$, and $n = n_1 + n_2$.

To test the hypothesis $H_0: p_1 = p_2$ against $H_1: p_1 \neq p_2$, Donner^[1] and Donner and Banting^[2] proposed the adjusted χ^2 statistic which is an adjustment of usual Pearson chi-square statistic based on an empirical estimate of the intraclass correlation coefficient,

$$X_U^2 = X_1^2/C_1 + X_2^2/C_2,$$

where

$$X_k^2 = (y_k - M_k \hat{p})^2 / M_k \hat{p} + (M_k - y_k - M_k \hat{q})^2 / M_k \hat{q}$$

$$C_k = 1 + \left(\sum_{i=1}^{n_k} m_{ki}^2 / M_k - 1 \right) \hat{\rho},$$

$\hat{p} = (y_1 + y_2)/M$ and $\hat{q} = 1 - \hat{p}$. Here, $\hat{p}$ is the analysis of variance (ANOVA) estimator for the intraclass correlation coefficient (ICC), ρ , given by

$$\hat{\rho} = \frac{\text{msc} - \text{mse}}{\text{msc} + (\tilde{m} - 1)\text{mse}},$$

where

$$\text{msc} = \sum_{k=1}^2 \sum_{i=1}^{n_k} m_{ki} (\hat{p}_{ki} - \hat{p}_k)^2 / (n - 2),$$

$$\text{mse} = \sum_{k=1}^2 \sum_{i=1}^{n_k} y_{ki} (1 - \hat{p}_{ki}) / (M - n),$$

$$\tilde{m} = (M - \sum_{k=1}^2 M_k^{-1} \sum_{i=1}^{n_k} m_{ki}^2) / (n - 2), \hat{p}_{ki} = y_{ki} / m_{ki} \quad \text{and} \quad \hat{p}_k = y_k / M_k.$$

The adjusted χ^2 statistic, χ_U^2 , assigns an equal weight to each subunit. Equal weights to subunits are interpreted as weights to clusters proportional to the cluster size.

As an alternative method, Lee and Dubin^[3] and Lee^[4] proposed to assign equal weights to clusters regardless of the cluster size. This weighting system avoids the dominance of a few clusters with large number of observations in the sample. In this case, p_k is estimated by the simple average of a response rate of each cluster in group k ,

$$\tilde{p}_k = \frac{\sum_{i=1}^{n_k} \tilde{p}_{ki}}{n_k}.$$

A variance estimator for $\tilde{p}_k$ is given as

$$\tilde{u}_k = \frac{\sum_{i=1}^{n_k} (\tilde{p}_{ki} - \tilde{p}_k)^2}{n_k (n_k - 1)}.$$

We can show that $\tilde{p}_k$ is consistent and approximately normal with mean p_k and estimated variance $\hat{v}_k$. Therefore, the weighted χ^2 statistic, X_C^2 which assigns an equal weight to each cluster, can be written as

$$X_C^2 = \frac{(\tilde{p}_1 - \tilde{p}_2)^2}{\tilde{v}_1 + \tilde{v}_2},$$

Note that these two weighting methods are identical if all clusters have equal cluster size. Jung and Ahn^[5] introduced an optimal weighting method reflecting the amount of intraclass correlation when the cluster size is varying among clusters. For group k , let $(w_{k1}, w_{k2}, \dots, w_{kn_k})$ be a set of weights such that $w_{ki} \geq 0$ and $\sum_{i=1}^{n_k} w_{ki} = 1$. The optimal weight estimator is given as

$$\bar{p}_k = \sum_{i=1}^{n_k} w_{ki} \hat{p}_{ki}.$$

where

$$w_{ki} = \bar{\sigma}_{ki}^{-2} / \sum_{i=1}^{n_k} \bar{\sigma}_{ki'}^{-2},$$

$$\bar{\sigma}_{ki}^2 = \frac{\bar{s}^2 + (m_{ki} - 1)\bar{c}_k}{m_{ki}},$$

$$\bar{s}^2 = \bar{p}(1 - \bar{p}),$$

and

$$\bar{c}_k = \sum_{i=1}^{n_k} \frac{y_{ki}(y_{ki} - 1)}{m_{ki}(m_{ki} - 1)} - \bar{p}^2$$

The optimal estimator $\bar{p}_k = \sum_{i=1}^{n_k} w_{ki} \hat{p}_{ki}$ is consistent and approximately normal with mean p_k and variance $\bar{v}_k = (\sum_{i=1}^{n_k} \bar{\sigma}_{ki}^{-2})^{-1}$, so that

$$Z = \frac{\bar{p}_1 - \bar{p}_2}{\sqrt{\bar{v}_1 + \bar{v}_2}}$$

follows a normal distribution with mean 0 and variance 1 under $H_0: p_1 = p_2$. Based on these results, Ahn, Jung, Kang^[8] propose a modified χ^2 statistic using the optimal weights

$$X_o^2 = \frac{(\bar{p}_1 - \bar{p}_2)^2}{\bar{v}_1 + \bar{v}_2},$$

If the cluster size is constant for each arm (i.e. $m_{ki} = m_k$), then all three test statistics are identical.

Example 1

As a real study example, we take a teratologic animal study (Weil^[9]) that has been analyzed by several authors including Williams^[10], and Ochi and Prentice^[11]. In this study, 32 pregnant rats were randomly assigned to either receive a control diet ($n_1 = 16$) or a chemically treated diet ($n_2 = 16$) during pregnancy and lactation, see Table 1. This is an animal study, but its statistical design is very similar to that of a randomized clinical trial. The 21-day survival rates among the pups in each litter are shown in Table 4 for the control and treatment groups. The estimated 21-day survival rates (p_1, p_2) for two groups are (0.899, 0.772) using equal weights to the subunits, (0.893, 0.746) using equal weights to cluster, and (0.898, 0.750) using the optimal weights. The purpose of the study is to examine if the rats in the treatment group have significantly lower survival rate than those in the control group.

For the data set, ICC is 0.03 for the control and 0.37 for the treatment group. Williams^[10] noted that the ICC of the treatment group is substantially higher than that of the control group, possibly due to treatment effect. Jung, Ahn and Donner^[12] proposed the conditions for checking the validity of X_U^2 . Even though the ICC is substantially different between the two groups, it can be shown that X_U^2 satisfies the validity conditions for the analysis of this toxicological data. So, the use of a common ICC, $\hat{p} = 0.25$, remains appropriate purpose of testing the null hypothesis.

The estimated imbalance parameter, $\hat{k}$, is 0.95 in this data set. The weighted chi-square statistics (and p-values) for

testing equal survival probability between two groups are $X_C^2 = 2.582(p = 0.108)$, $X_U^2 = 2.761(p = 0.097)$, and $X_O^2 = 3.554(p = 0.059)$. These results suggest that there is no significant difference in 21-day survival rate between the two groups at two-sided $\alpha = 0.05$ level.

2.2 Under Subunit Randomization

Under subunit randomization, we use slightly different notations or the same notations with different definitions from those under cluster randomization. Suppose that there are n clusters, and cluster $i (= 1, \dots, n)$ has m_i subunits of which m_{ki} are randomized to arm $k (= 1, 2)$, $m_i = m_{1i} + m_{2i}$. Under subunit randomization, subunits of each cluster are allocated to different arms, so that there exist dependent observations both in each arm and among different arms. Let y_{kij} denote a binary variable indicating a response ($y_{kij} = 1$) or no response ($y_{kij} = 0$) for subunit $j (= 1, \dots, m_{ki})$ randomized to arm $k (= 1, 2)$ from cluster $i (= 1, \dots, n)$ with $P(y_{kij} = 1) = p_k$. Let $y_{ki} = \sum_{j=1}^{m_{ki}} y_{kij}$, $y_k = \sum_{i=1}^n y_{ki} = \sum_{i=1}^n \sum_{j=1}^{m_{ki}} y_{kij}$, $M_k = \sum_{i=1}^n m_{ki}$, and $M = M_1 + M_2$.

At first, we consider estimating p_k by assigning equal weight to subunits using

$$\hat{p}_k = \frac{y_k}{M_k} = \frac{\sum_{i=1}^n y_{ki}}{M_k},$$

and testing the hypothesis $H_0: p_1 = p_2$ against $H_1: p_1 \neq p_2$ using $\hat{p}_1 - \hat{p}_2$. Under H_0 ,

$$\hat{p}_1 - \hat{p}_2 = \sum_{i=1}^n \left(\frac{y_{1i} - m_{1i}p_1}{M_1} - \frac{y_{2i} - m_{2i}p_2}{M_2} \right) = \sum_{i=1}^n \epsilon_i,$$

where $\epsilon_i = M_1^{-1}(y_{1i} - m_{1i}p_1) - M_2^{-1}(y_{2i} - m_{2i}p_2)$ are 0 mean independent random variables. So, under H_0 by the central limit theorem, $\hat{p}_1 - \hat{p}_2$ is approximately normal with mean 0 with variance that can be estimated by

$$\hat{v} = \sum_{i=1}^n \hat{\epsilon}_i^2,$$

where $\hat{\epsilon}_i = M_1^{-1}(y_{1i} - m_{1i}\hat{p}_1) - M_2^{-1}(y_{2i} - m_{2i}\hat{p}_2)$. Hence, a modified χ^2 test can be obtained as

$$X_U^2 = \frac{(\hat{p}_1 - \hat{p}_2)^2}{\hat{v}}.$$

Table 1 Number, y , of pups that survived the 21-day lactation period and the number, m , of pups alive at 4 days for each litter

Group	(y, m)							
Control	(13, 13)	(12, 12)	(9, 9)	(9, 9)	(8, 8)	(8, 8)	(12, 13)	(11, 12)
	(9, 10)	(9, 10)	(8, 9)	(11, 13)	(4, 5)	(5, 7)	(7, 10)	(7, 10)
Treated	(12, 12)	(11, 11)	(10, 10)	(9, 9)	(10, 11)	(9, 10)	(9, 10)	(8, 9)
	(8, 9)	(4, 5)	(7, 9)	(4, 7)	(5, 10)	(3, 6)	(3, 10)	(0, 7)

An estimator of p_k assigning equal weights to clusters is given as

$$\tilde{p}_k = \frac{\sum_{i=1}^n \hat{p}_{ki}}{n}.$$

Under H_0 ,

$$\tilde{p}_1 - \tilde{p}_2 = \frac{1}{n} \sum_{i=1}^n (\hat{p}_{1i} - \hat{p}_{2i}) = \sum_{i=1}^n e_i,$$

where $e_i = n^{-1}(\hat{p}_{1i} - \hat{p}_{2i})$ are 0 mean independent random variables. So, by the central limit theorem, $\tilde{p}_1 - \tilde{p}_2$ is approximately normal with mean 0 with variance that can be estimated by

$$\hat{v} = \sum_{i=1}^n e_i^2$$

under H_0 . Hence, a modified χ^2 test can be obtained as

$$X_C^2 = \frac{(\tilde{p}_1 - \tilde{p}_2)^2}{\hat{v}}.$$

Now we derive optimal weights for a modified χ^2 test. Under subunit randomization, we consider

$$W = \sum_{i=1}^n w_i (\hat{p}_{1i} - \hat{p}_{2i})$$

for $w_i \geq 0$ and $\sum_{i=1}^n w_i = 1$. Since, for $i = 1, \dots, n$, $\hat{p}_{1i} - \hat{p}_{2i}$ are independent 0 mean random variables under H_0 , by the central limit theorem, W is approximately normal with mean 0 and variance that can be approximated by

$$\bar{v} = \sum_{i=1}^n w_i^2 (\hat{p}_{1i} - \hat{p}_{2i})^2.$$

In order to minimize $\bar{v}$, we use the inverse of the variance of $\hat{p}_{1i} - \hat{p}_{2i}$ as the weight w_i . Let $\sigma_k^2 = p_k(1 - p_k)$, and $\rho_0 = \text{corr}(y_{1ij}, y_{2ij})$, the correlation coefficient between two subunits that are assigned to different treatment arms, and $\rho_k = \text{corr}(y_{kij}, y_{kij})$, the correlation coefficient between two subunits that are assigned to the same treatment arms from each cluster. Then,

$$\hat{p}_{1i} - \hat{p}_{2i} = \frac{1}{m_{1i}} \sum_{j=1}^{m_{1i}} y_{1ij} - \frac{1}{m_{2i}} \sum_{j=1}^{m_{2i}} y_{2ij}$$

has variance

$$s_i^2 = \frac{\sigma_1^2}{m_{1i}} \{1 + (m_{1i} - 1)\rho_1\} + \frac{\sigma_2^2}{m_{2i}} \{1 + (m_{2i} - 1)\rho_2\} - 2\rho_0\sigma_1\sigma_2.$$

Note that σ_k^2 , ρ_0 and ρ_1 can be consistently estimated by $\hat{\sigma}_k^2 = \hat{p}_k(1 - \hat{p}_k)$,

$$\bar{\rho}_0 = \frac{\bar{c}_{12}}{\hat{\sigma}_1 \hat{\sigma}_2}$$

and

$$\bar{\rho}_k = \frac{\bar{c}_k}{\hat{\sigma}_k^2}$$

respectively, where

$$\bar{c}_{12} = \frac{\sum_{i=1}^n \sum_{j=1}^{m_{1i}} \sum_{j'=1}^{m_{2i}} (y_{1ij} - \hat{p}_1)(y_{2ij'} - \hat{p}_2)}{\sum_{i=1}^n m_{1i} m_{2i}}$$

is a consistent estimator of the covariance between two subunits assigned to different treatment arms from the same cluster and

$$\bar{c}_{12} = \frac{\sum_{i=1}^n \sum_{j=1}^{m_{ki}} \sum_{j'=1}^{m_{ki}} (y_{kij} - \hat{p}_k)(y_{kij'} - \hat{p}_k)}{\sum_{i=1}^n m_{ki}(m_{ki} - 1)}$$

is a consistent estimator of the covariance between two subunits assigned to treatment arm k from the same cluster. We obtain $\bar{s}_i^2$ from s_i^2 by replacing σ_k^2 , ρ_0 and ρ_k with their consistent estimators $\hat{\sigma}_k^2$, $\bar{\rho}_0$ and $\bar{\rho}_k$, respectively. Finally, we obtain an optimal weights

$$w_i = \frac{\bar{s}_i^{-2}}{\sum_{i'=1}^n \bar{s}_{i'}^{-2}}$$

and an optimal χ^2 test

$$X_O^2 = \frac{W^2}{\bar{v}} = \frac{\left\{ \sum_{i=1}^n w_i (\hat{p}_{1i} - \hat{p}_{2i}) \right\}^2}{\sum_{i=1}^n w_i^2 (\hat{p}_{1i} - \hat{p}_{2i})^2}.$$

If the cluster size is constant (i.e. $m_i = m$) and the allocation proportion is fixed (i.e. m_{1i}/m_{2i} is identical for all clusters), then the all three test statistics are identical.

Example 2

The data, shown in Table 2, consist of survival times (days) of closely ($k = 1$) and poorly ($k = 2$) matched skin grafts on each burned patient. We want to test if the probability that the survival time is longer than or equal to 30 days or not between closely and poorly matched skin grafts. We have $\hat{p}_1 = 0.32$, $\hat{p}_2 = 0.14$, $X_U^2 = 3.126$ (p-value = 0.077) using equal weights to subunits, $\hat{p}_1 = 0.42$, $\hat{p}_2 = 0.18$, $X_C^2 = 2.286$ (p-value = 0.131) using equal weights to clusters, and $X_O^2 = 2.650$ (p-value = 0.104). Since too

Table 2 Days of skin graft survival on each burned patient

Patient	1	2	3	4	5	6	7	8	9	10	11

+ indicates censored observations.

few patients have multiple grafts within each graft group, the estimator $\bar{\rho}_k$ may not be reliable enough, so that the optimal χ^2 does not have more significance than that using equal weights for subunits.

3 SIMULATION STUDIES

At first, we conduct some simulations. We set the number of clusters at $n_1 = n_2 = 10, 20, 30$. For cluster i ($i = 1, \dots, n_k$) in arm k ($k = 1, 2$), the cluster size m_{ki} is generated from a negative binomial distribution truncated below 1. We used the methodology proposed by Donner and Koval^[13] where the cluster size m_{ki} is generated from the negative binomial distribution truncated below 1 with parameters s and P . This distribution is

$$P_{(m)} = \frac{(s+m-1)!Q^{-s}(P/Q)^m}{(s-1)!m!(1-Q^{-s})},$$

where $Q = 1 + P$, $m = 1, 2, \dots$.

From the parameters of this distribution, we can derive new parameters that describe the variability of the cluster size. By Johnson and Kotz^[14], the mean and variance of this distribution are $\mu = sP/(1 - P_0)$ and $\sigma^2 = \mu[1 + P - sP P_0/(1 - P_0)]$, where $P_0 = (1 + P)^{-s}$. The measure of imbalance is given by $\kappa = 1/(1 + \nu^2)$, where ν is the coefficient of variation, that is, $\nu = \sigma/\mu$. It is clear that κ equals 1 when all the cluster sizes are identical. We have a relationship between the variance and the imbalance parameter, $\sigma^2 = \mu^2(1 - \kappa)/\kappa$. The variance of cluster size decreases in κ . Table 3 provides the value of κ under various design settings with $n = 10$. We use numerical methods to obtain the values of s and P corresponding to specified values of μ and κ .

Once the cluster size, m_{ki} , is obtained, a random variable y_{ki} is generated from a beta-binomial distribution with true success probability p_k for clusters in group k and an ICC $\rho_1 = \rho_2 = \rho = 0.05, 0.1, 0.2, 0.3$. In order to study the effect of varying the degree of imbalance (κ) on the performance of the estimators, we vary κ over a specified range for a mean cluster size μ . We allow the cluster size to vary with a mean cluster size of $\mu = 10$, and the imbalance parameter of $\kappa = 0.6, 0.7, 0.8$, and 0.9 .

We compute the empirical type I error and power X_U^2, X_C^2 , and X_O^2 , by running 5,000 simulations for each combination of parameters. Table 4 shows the empirical type I error rates for testing $H_0: p_1 = p_2 (= p)$ under $p = 0.1, 0.3$, or 0.5 . The weighted chi-square statistics, X_U^2 and X_O^2 , are slightly anti-conservative when $n_1 = n_2 = 10$. When $n_1 = n_2 = n = 20$ or 30 , all the weighted chi-square statistics have empirical type I errors close to 5% significance level and the differences in empirical type I errors are negligible among weighted chi-square statistics considered here. Table 5 shows the empirical powers for testing $H_0: p_1 = p_2$ under $p_1 = 0.1, 0.3$ or 0.5 , and $p_2 = p_1 + 0.2$. The optimal weight chi-square statistic, X_O^2 , yields higher empirical power levels than X_U^2 and X_C^2 . When $n_1 = n_2 = 10$, X_C^2 performs better in empirical type I errors than X_U^2 and X_O^2 . However, X_C^2 has lowest powers among weighted chi-square statistics

considered here. As the imbalance parameter (κ) increases, the variability in cluster size decreases and the empirical power increases. The difference in empirical power between X_O^2 and the other two weighted chi-square statistics increases as the variability in cluster size increases. Table 5 shows that the empirical power increases as the number of clusters n_k increases. As the ICC ρ decreases, the empirical power increases. Based on the results from the simulation study, we recommend using X_O^2 because of its higher power compared to the other weighted chi-square tests.

Abstract

This entry presents the semiparametric model of stability analysis and discusses the rank-based inference procedures to determine the shelf-life of drug products.

Keywords: Expiration dating period; Rank regression; Semiparametric; Model; Shelf-life; Stability analysis.

INTRODUCTION

In the pharmaceutical industry, stability study is performed to determine the shelf-life of drug product. It provides the assurance that the capacity of a drug product maintains its identity, strength, quality, and purity before the drug expiration date. The stability data are often collected on the product samples stored in controlled conditions to measure the drug characteristics changing over time.

As indicated in a draft consensus guideline of *Evaluation of Stability Data* issued by the International Conference on Harmonization (ICH) Steering Committee (2002),^[1] “regression analysis is considered an appropriate approach to evaluating the stability data for a quantitative attribute and establishing a retest period or shelf life” (p. 6). However, most of these regression models rely heavily on their underlying parametric assumptions, such as normality of the continuous characteristics or their transformations. In this article, the alternative approach, semi-parametric regression models, is presented. The rank-based inference procedures to determine shelf-life are discussed. Numerical studies including Monte Carlo simulations and practical examples are demonstrated as well.

STABILITY ANALYSIS BASED ON RANK REGRESSION

Semiparametric Regression Models

In the FDA’s 1987 guideline,^[2] the linear regression models shown in Eq. 1 were used in the stability analysis. Denote

Y_{ij} the continuous outcome of the characteristic for the j th measurement of the i th batch, $i = 1, 2, \dots, n$, and $j = 1, 2, \dots, m_i$.

$$Y_{ij} = \alpha_i + \beta_i X_{ij} + e_{ij} \quad (1)$$

where X_{ij} are the associated covariates, $(\alpha_i, \beta_i)^T$ are the parameters, and e_{ij} are the independent random errors. The random errors are assumed to be identically zero-mean normal deviates with constant standard variance σ_e^2 . The superscript T denotes the transpose of vector or matrix.

However, it is well known that the fully parametric approaches in Eq. 1 have to depend heavily on the validity of their parametric assumptions. Without strong belief in these assumptions, the following alternative semiparametric model can be considered:

$$h(Y_{ij}) = \alpha_i + \beta_i X_{ij} + e_{ij} \quad (2)$$

where e_{ij} are independent zero-mean deviates with an unknown density function of $f(\cdot)$, and $h(\cdot)$ is some known monotonic transformation function.

Note that the model in Eq. 2 is quite flexible without assuming the underlying distribution of normality or constant variance. Moreover, there is no assumption on the parametric distributions on $(\alpha_i, \beta_i)^T$ as random effects but leaving them as fixed effects, when appropriate rank-based inference procedures discussed later are utilized. Additionally, the parametric component in Eq. 2 is still the linear combination of parameter β_i and covariates X_{ij} . So the sign and quantity of β_i characterize the direction and magnitude of the linear trend of Y_{ij} with respect to X_{ij} , respectively.

For example, when X_{ij} are the times at which Y_{ij} are measured, β_i may stand for “degradation” of measurements over time for its negative sign.

RANK-BASED SHELF-LIFE DETERMINATION

Shelf-Life for a Single Batch

Considering one single batch of stability data for stability analysis, $n = 1$. Without loss of generality, assume $h(\cdot)$ is an identity link. Eq. 2 becomes $Y_j = \alpha + \beta X_j + e_j$. Under the null hypothesis of $\beta = 0$, a standard rank test statistic is $U = \sum_{j=1}^m (X_j - \bar{X})R(Y_j)$ where $\bar{X}$ is the mean of X , and $R(Y_1), R(Y_2), \dots, R(Y_m)$ are the ranks of $Y_1, Y_2, \dots, Y_m$, respectively. When β is not necessarily zero, the residuals of $e_j = Y_j - (\alpha + \beta X_j)$ are considered $U(\beta) = \sum_{j=1}^m (X_j - \bar{X})R(e_j)$. Apparently, $E[U(\beta); \beta] = 0$ for any $\beta \in \mathbf{B} \subset \mathbf{R}$, where $\mathbf{B}$ is the parameter space and $\mathbf{R}$ is the real line. Therefore β is estimated by solving the unbiased estimating equation $U(\beta) = 0$. It is noticeable that the parameter of α is not estimable from $U(\beta)$, because it serves as a baseline effect for every observation and therefore the ranks are invariant to the constant intercept. One remedy to determine α is using the median of $(Y_j - \beta X_j), j = 1, 2, \dots, m$. When the distribution of error terms is further symmetric, α can be estimated by the median of the Walsh average of residuals of $(e_i + e_j)/2, 1 \leq i < j \leq m$.^[3,4]

As $U(\beta)$ is a monotonically decreasing step function in β , there may not exist values of β to allow $U(\beta) = 0$ exactly. One approach is to define $\hat{\beta}$ that satisfies $U(\hat{\beta}+)U(\hat{\beta}-) \leq 0$. The other alternative is to obtain the rank estimate $\hat{\beta}$ by minimizing the $D(\beta) = \sum_{j=1}^m w_j \{R(e_j)\} e_j$ where $w_j(\cdot)$ are the nonconstant sequence of scores such that $w_j + w_{m-j+1} = 0$.^[5] Then $D(\beta)$ is a nonnegative, continuous, and convex function of β . Specifically, consider the Wilcoxon scores of $w(j) = \phi\{j/(m+1)\}$, where $\phi(u) = \sqrt{12}(u - 1/2)$. Let β_0 be the true value of β . According to the regularity conditions and Theorem 5.2.3 in Ref. [3], $m^{1/2}(\hat{\beta} - \beta_0) \xrightarrow{D} N(0, \tau^2 - 1)$ where $\tau^2 = (\sqrt{12} \int_0^1 f^2(u) du)^{-1}$ and $\Sigma = \lim_{m \rightarrow \infty} m^{-1} X_c' X_c$ is to be positive-definite. Here X_c is the centered X by $X_c = X - 1(\bar{x}_1, \bar{x}_2, \dots, \bar{x}_p)$, where $\bar{x}_i$ is the mean of the i th column in X . Furthermore, when $\hat{\alpha}$ is the median of $\hat{e}_j = Y_j - \hat{\beta} X_j$, it can be shown that $m^{1/2}[(\hat{\alpha}, \hat{\beta})^T - (\alpha_0, \beta_0)^T]$ would have an asymptotic distribution of multivariate normal with mean zero and variance-covariance of $V = \tau^2 \begin{bmatrix} 2f(0)\tau^{-2} + \mu^T - 1 & \mu^T - 1 \\ -\mu^T - 1 & -1 \end{bmatrix}$ where μ is the mean vector of Y 's, and $f(\cdot)$ is the density function of e_j 's. When $\hat{\alpha}$ is the median of the Walsh averages, $m^{1/2}[(\hat{\alpha}, \hat{\beta})^T - (\alpha_0, \beta_0)^T]$ follows an asymptotic distribution of multivariate normal with mean zero and variance-covariance of $V = \tau^2 \Lambda^{-1}$ where $\Lambda^{-1} = \lim_{m \rightarrow \infty} [1, X]^T [1, X]$. Here $\mathbf{1}$ is a unit vector and $\mathbf{X}$ the design matrix.

As a result, an approximately 95% pointwise confidence bound for EY is then (LB, UB), where

$$LB = \hat{\alpha} + \hat{\beta} X + Z_{0.025} \sqrt{(1, X) \hat{V}(1, X)^T} \quad \text{and} \quad UB = \hat{\alpha} + \hat{\beta} X + Z_{0.975} \sqrt{(1, X) \hat{V}(1, X)^T}$$

Therefore an estimate of shelf-life is the point of time, T_{shelf} , at which LB or UB intersects the predefined most allowable specification, η , say, depending on whether β is negative or positive, respectively.

Shelf-Life for Multiple Batches

According to the FDA's 1987 guideline, at least three batches are preferable to allow the estimate of batch-to-batch variation in stability analysis. When the batch-to-batch variation is suspected, there are three occasions from batch-to-batch:

- Different intercepts, but same slope.
- Different slopes, but same intercept.
- Both intercepts and slopes are different.

The estimation equations along with the estimates of α and β of three occasions, and shelf-life determination are discussed as below.

When the batch-to-batch variation is present as in occasion (1): $Y_{ij} = \alpha_i + \beta X_{ij} + e_{ij}$ where β is the common slope for every batch. The estimation equation is $U(\beta) = \sum_{i=1}^n U_i$ where $U_i = \sum_{j=1}^{m_i} i(X_{ij} - \bar{X}_i)R(e_{ij})$. Here $\bar{X}_i = m_i^{-1} \sum_j X_{ij}$ and $e_{ij} = Y_{ij} - (\alpha_i + \beta X_{ij})$. Similarly, the medians of $Y_{ij} - \beta X_{ij}, j = 1, 2, \dots, m_i$, can be used to estimate $\alpha_i, i = 1, \dots, n$, individually.

When the batch-to-batch variation is present as in occasion (2): $Y_{ij} = \alpha + \beta_i X_{ij} + e_{ij}$ where α is the common intercept for every batch. To estimate individual β_i , consider: $U_i(\hat{\beta}_i) = 0$ for every individual i to solve for $\hat{\beta}_i$. Then the medians of $Y_{ij} - \hat{\beta}_i X_{ij}, j = 1, 2, \dots, m_i, i = 1, \dots, n$, are used to estimate α .

When the batch-to-batch variation is present as in occasion (3): $Y_{ij} = \alpha_i + \beta X_{ij} + e_{ij}$ where the intercepts and slopes are both different from batch-to-batch. To estimate individual β_i , consider: $U_i(\hat{\beta}_i) = 0$. And the medians of $Y_{ij} - \hat{\beta}_i X_{ij}, j = 1, 2, \dots, m_i, i = 1, \dots, n$, respectively.

If the batch-to-batch variation exists, the straightforward approach is to use the minimum approach required by the FDA's guidelines. That is, first compute $T_{\text{shelf}, i}$ for each individual batch, and the final shelf-life is then $\min(T_{\text{shelf}, i}, i = 1, 2, \dots, n)$. Or, when the number of batches is large enough and, potentially, the so-called “future” batches show variability, then the shelf-life can be computed based on the prediction bounds of the average values of α_i and β_i , following the approach by Shao and Chen.^[6] If in fact, α_i 's are random effects, the randomness of α_i still has an impact on the asymptotic distribution of the slope estimates. In this case, the parameter τ and the joint distribution of the intercepts and slopes will need to be modified.^[7]

PRELIMINARY TEST FOR BATCH SIMILARITY

The batch similarity can be evaluated by the following null hypotheses of testing the equality of slopes and intercepts among batches. $H_{\alpha:\beta} : \beta_i = \beta_{i'} \text{ for all } i \neq i'$. $H_{\alpha:\alpha} : \alpha_i = \alpha_{i'} \text{ for all } i \neq i'$. To test the batch-to-batch variation, the method in Ref. [8], which is similar to the Woolf's test for stratified samples in homogeneity, can be extended to the obtained rank-based estimates. Let $(\hat{\alpha}_i, \hat{\beta}_i)$ be the estimates of (α_i, β_i) for individual batch i based on the methods discussed before. Let $(\hat{\alpha}, \hat{\beta})$ be one estimate by pooling all the batches together, i.e., without batch-to-batch variation. Then the statistics $TS = \sum_{i=1}^n (\hat{\alpha}_i - \hat{\alpha}, \hat{\beta}_i - \hat{\beta})^T \hat{V}_i^{-1} (\hat{\alpha}_i - \hat{\alpha}, \hat{\beta}_i - \hat{\beta})$ where $\hat{V}_i$ are the estimates of the variance of $(\hat{\alpha}_i, \hat{\beta}_i)$, respectively, under the null hypothesis that there is no batch-to-batch variations. It follows a χ^2 -distribution with degrees of freedom of $n - 1$ approximately. The null hypothesis is rejected if the associated p -value is larger than 0.25 as in the current guideline from FDA.

NUMERICAL STUDIES

The computation of the proposed rank-based approaches is tedious especially when the covariates are of relatively higher dimensions. In this case, the "recursive bisection" programming^[9] can be used to solve the estimating function. To compute $\hat{V}$ of the confidence bands of (LB, UB), $\hat{\tau}$ can be estimated by $\int f^2(u) du$,^[10] which is by obtaining a kernel type of estimate of $f(u)$: $f(u) = \frac{1}{mh} \sum_{j=1}^m k\left(\frac{u - e_j}{h}\right)$ where $k(\cdot)$ is a uniform kernel function $k(u) = \frac{1}{2} \quad u \in [-1/2, 1/2]$ and 0 otherwise and h is kernel bandwidth. Then $\delta = \int f^2(u) du = \int f(u) dF(u)$ can be estimated by $\hat{\delta} = \frac{1}{m^2 h} \sum_{i=1}^m \sum_{j \neq i}^m I\left(\pi |e_i - e_j| \frac{h}{2}\right)$ Hettmansperger^[3] proposed a modified version of $\hat{\delta}_c$ to ease the computation, such that $\hat{\delta}_c = \frac{1}{mc} + \frac{1}{m(m-1)h} \sum_{i=1}^m \sum_{j \neq i}^m k\left(\frac{e_i - e_j}{h}\right)$ where c is any fixed constant. The modified $\hat{\delta}_c$ is also consistent with δ when $h = cm^{-1/2}$ (Theorem 5.2.4 in Ref. [3]), The actual implement of $\hat{\delta}_c$ can be found in Ref. [7].

In the simulations, the performance of rank-based estimation procedure under different error structures based on a common slope model shown below is considered: $Y_{ij} = \alpha_i + \beta X_{ij} + e_{ij}$ for $i = 1, \dots, n$ and $j = 1, \dots, m$ where Y_{ij} is the characteristic of interest of the j th measurement for the i th batch, X_{ij} is the time of the j th measurement for the i th batch, e_{ij} is the random error of the j th measurement for the i th batch, α_i is the batch-specific intercept, and β is the common slope.

Considering the FDA's (1987) recommendation of at least three batches to obtain the shelf-life for an NDA submission, both $n = 1$ and 3 are performed in the simulation

study. The slope is defined as $\beta = -0.5$, i.e., 0.5 unit decreasing change per month. In addition, $\alpha = 100$ for $n = 1$ and $\alpha = \{100, 101, 102\}$ for $n = 3$. The sampling time points in month are based on a full FDA sampling plan, i.e., $x = (0, 3, 6, 9, 12, 18)$. There are three error distributions considered in the simulation:

- Normal [$e_{ij} \approx N(0, 1)$]
- Uniform [$e_{ij} \approx U(-2, 2)$]
- Log-normal [$\log e_{ij} \approx N(0, 1)$]

One thousand sets of data for each error distribution and for number of batch $n = 1$ and $n = 3$, respectively. The mean and standard deviation of the estimated intercepts and slopes are summarized in Table 1. It is noticeable that the parameter estimates of rank regression models are comparable in terms of efficiency with those of normal linear regression models with the ordinary least squares (OLS) for data with normal errors, or other errors that do not deviate much from normal errors. The OLS estimates for normal linear models tend to be a bit more efficient than the rank regression estimates with the normal assumption. This can be seen from their smaller standard deviations. However, the rank regression is more robust and efficient for data with errors that deviate much from normal errors.

ALTERNATIVE APPROACHES

In addition to the approach outlined in the previous sections, there are also some other rank-based methods that can be used in stability analysis as well. For a specific example, consider the model in the special single-batch occasion, $Y_j = \alpha + \beta X_j + e_j$. As assumed, the random errors are identically distributed; therefore any pair of (e_i, e_j) are comparable, in the sense that $E\{I(e_i e_j)\} = 1/2$. Therefore the following estimating equations can be used to reasonably estimate the slope parameter of β :

$$U(\hat{\beta}) = \sum_{i=1}^n \sum_{j=i+1}^n I[y_i - y_j - \beta(x_i - x_j) \leq 0] - (n^2 - n)/4 = 0$$

It is not difficult then to show that $E[U(\beta)] = 0$ and $\text{var}[U(\hat{\beta})] = \text{var}\left[\sum_{i=1}^n \sum_{j=i+1}^n I(e_i \leq e_j)\right] = (n^2 - n)/8$. To estimate the intercept α , the similar estimator of the medians of $Y_i - \beta X_i$ can be used as $\hat{\alpha}$.

For the three different situations in the presence of the batch-to-batch variations, the above estimating equations can be modified accordingly to estimate the slopes and intercepts, as was done in the previous sections similarly.

In addition to the exact method to compute the confidence intervals, a bootstrap method can be also used to obtain the confidence intervals. Specifically,

Table 1 Mean and Standard Deviation of Estimated Model Parameters

Parameter		$e_{ij} \approx N(0,1)$	$e_{ij} \approx U(-2,2)$	$e_{ij} \approx N(0,1)$
[$n = 1$]

NLM	B	-0.4994 (0.0316)	-0.5012 (0.0359)	-0.4997 (0.0623)
[$n = 3$]				
RRM	α_1	99.9860 (0.5051)	100.0252 (0.6642)	101.0751 (0.4958)
RRM	α_2	100.9893 (0.5012)	101.0363 (0.6622)	102.1150 (0.5241)
RRM	α_3	101.9936 (0.4877)	102.0038 (0.6615)	103.1259 (0.5476)
RRM	B	-0.4996 (0.0193)	-0.4998 (0.0227)	-0.4981 (0.0182)
NLM	α_1	99.9915 (0.4411)	100.0097 (0.4955)	101.6286 (0.9150)
NLM	α_2	100.9961 (0.4302)	101.0180 (0.4847)	102.6333 (0.9056)
NLM	α_3	101.9827 (0.4275)	102.0043 (0.4960)	103.6305 (0.8960)
NLM	B	-0.4995 (0.0176)	-0.4997 (0.0205)	-0.4993 (0.0382)

RRM: Rank regression model. NLM: Normal linear model (fitted by OLS). Standard deviations are enclosed in parenthesis. $n = 1$ or 3 represents number of batches. True parameters are $\beta = -0.5$, $\alpha = 100$ for $n = 1$; and $\alpha_1 = 100$, $\alpha_2 = 101$, and $\alpha_3 = 102$ for $n = 3$.

1. For a batch data i , m_i pairs of (x_a, x_b) are picked randomly with replacement.
2. Use the proposed method to get $\hat{\beta}$.
3. Repeat the above two steps for B times, thus we have $\hat{\beta}_b$ for $b = 1, 2, \dots, B$.
4. Take the 2.5 percentile of $\hat{\beta}_b$ as the lower confidence bound.
5. $\hat{\alpha}$ is estimated as the median of $Y_i - \hat{\beta}_{LB} X_i$.
6. For a continuous X^* including the range of X , the estimate of Y^* is computed as: $Y^* = \hat{\alpha} + \hat{\beta}_{LB} X^*$.
7. The time at which Y^* intersects the prespecified limit is the shelf-life.

Simulations have been conducted to verify the validity of the alternative approaches. Similar results were obtained with the data example in Ref. [11], which are consistent with the ones in Ref. [7].

CONCLUSION

The semiparametric regression models and their associated rank-based inference procedures in obtaining the shelf-life provide an alternative approach when the parametric assumptions are not true in the fully parametric models. Although they may carry disadvantages in efficiency when the parametric models may fit well, their flexibility to allow nonstandard continuous outcomes in stability data is appealing in practice when the regulatory agencies or drug manufacturers tend to be conservative in determining the shelf-life of actual products. In practical computing, the subroutines of PROC IML in SAS, such as NLPNMS (Nelder-Mead algorithm) and NLPQN (Quasi-Newton algorithm), can be used

to minimize $D(\beta)$ without requiring the second derivatives, and an updated estimator of τ can be found in Ref. [12].

The feature of the nonparametric components in this model also has profound practical interpretation. They do not need parametric assumptions. The proposed approaches do not explore the statistical justification whether or not the determined shelf-life estimates its true counterpart, but simply adopts the minimum approach of the FDA guidelines because of their simplicity and uniformity as an algorithm in choosing an intuitive shelf-life. Thus the results are also comparable to the available ones that conform to the FDA guidelines.

Regulatory Statistics

Estelle Russek-Cohen, Tsai-Lien Lin, and Shiohjen Lee

U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

Regulatory statistics is the scientific discipline consisting of the development and application of statistical methods, tools, approaches and other relevant processes derived from statistical science (and its sister disciplines) used to assess the safety, efficacy, quality and performance of regulated pharmaceutical products. In this article we highlight why such research is essential and touch on a number of topics in this arena. Finally we discuss topics in this area likely to gain prominence over the next few years.

Keywords: FDA; Innovative Trial Designs; PK and Bioequivalence; Postmarket Surveillance; Bayesian statistical methods; Biomarkers and Bioassays.

INTRODUCTION

Regulatory Science is “the science of developing new tools, standards and approaches to assess the safety, efficacy, quality and performance of FDA-regulated products”. Obviously such methods could be applicable to products regulated by FDA counterparts in other regions of the world.^[1]

Regulatory statistics is analogous. “Regulatory statistics is the scientific discipline consisting of the development and application of statistical methods, tools, approaches and other relevant processes derived from statistical science (and its sister disciplines) used to assess the safety, efficacy, quality and performance of FDA regulated products.” The definition is broad, its boundaries are vague and methods keep evolving.

In this article, we highlight areas of statistical research motivated by a regulatory need. In particular, we highlight areas that tend to have greater emphasis in a pharmaceutical regulatory environment though the US Food and Drug Administration (FDA) regulates more than just drugs and biologics. Statistical methods impact all aspects of product development ranging from pre-clinical, review of clinical trial protocols, marketing applications to post-market surveillance. Some of the assessments relate to manufacturing, evaluation of key biomarkers, and moving from pilot lots in pre-market studies to full production lots in post-market. However, many in the statistical community associate regulatory review at the FDA to be focused on clinical trials from trial design to trial outcomes.

The views expressed here are those of the authors and not necessarily those of the U.S. Food and Drug Administration.

Statisticians in a Regulatory Agency

Statisticians perform a key role in a regulatory agency such as the FDA. While they review protocols and results for many kinds of studies, they are in a position to identify gaps in statistical methodology; methodology and its consistency with policy and/or regulations; and make significant research contributions both in refereed journals and in regulatory guidance.

Guidances

There are many requirements for the approval of medical products at the FDA and key ones include those imbedded in the Code of Federal Regulations (e.g. 21CFR 314.126^[2] calls for adequate and well controlled studies). However in the need for transparency and to assist companies and FDA staff, current thinking is often documented in guidance and we will cite them as appropriate below. Each regulatory agency issues them (e.g. the FDA and its European counterpart the European Medicines Agency (EMA)). In addition, the International Council on Harmonization (ICH) develops guidelines that are recognized by multiple regulatory agencies. Among these, E9 Statistical Principles for Clinical Trials,^[3] is among the most cited.

FDA also participates in guideline development that is the result of public private partnerships, e.g. the US Pharmacopeia. The latter guidelines are mentioned in the discussions on statistical aspects of assessing non-clinical data below.

It should be noted that recommendations in guidance do not equate to regulation and companies can suggest alternatives in many situations.

STUDIES WITH ANIMAL MODELS

Pharmacology and toxicology studies in animals are required before the first-in-human trial. Depending on the product type and the intended population, other long term toxicology studies may need to be conducted at a later stage and submitted for marketing application, for example, carcinogenicity, genotoxicity and reproductive toxicity studies.^[4]

For vaccines or therapeutic products that cannot be evaluated for efficacy in humans (e.g. products to evaluate bioterrorism agents) there is the potential to be licensed or approved via the animal rule pathway, efficacy is demonstrated in proper animal models.^[5] Biomarkers that bridge data from animals to responses in humans often generate interesting statistical challenges. Note that safety for these products will need assessments in humans though that may not pose unique statistical challenges.

EARLY STAGE CLINICAL/DATA IN HUMANS

Prior to the approval of a drug or biologic product, there are often several development stages, in part because it would be unethical to expose a large number of subjects to an investigational product without a preliminary assessment of safety in humans. These sequential stages usually start from preliminary assessment of safety, to exploration of preliminary efficacy and additional safety data, and to the confirmation of safety and efficacy of the product. They are mostly referred to as Phase 1, Phase 2 and Phase 3; or early Phase and late Phase; or pilot Phase and pivotal Phase. Each stage has its role in product development. Depending upon how much we know about the investigational product, not all stages are needed prior to a product's approval. In this section we identify several major classes of studies along with some methodological concerns, some are randomized clinical trials but others are not.

Early Phase Exploratory Studies

Early phase studies are conducted to investigate an initial assessment of the safety and tolerability of the product, types of adverse events observed, and preliminary activity in treating disease. Often smaller studies are performed. The size of early phase studies may vary by therapeutic area but they are always smaller than confirmatory studies within the same area. Subjects in these studies may not be representative of the desired indication for use population, for example in early phase cancer studies, subjects may not have the same type of cancer or may be in very late stage of disease with no treatment options remaining. Often multiple doses are considered in early phase studies and Bayesian,^[6] frequentist and sometimes purely descriptive approaches are seen. In oncology^[7] therapeutic area, one goal of an early phase study is to identify the

maximum tolerated dose (MTD) but in studies for less serious conditions, the endpoints in these early phases are likely to differ.

Pharmacokinetic (PK) Studies

For new drugs and therapeutic proteins such as monoclonal antibodies, part of the requirement for submitting to FDA is a PK study that looks at the single-dose and/or steady-state concentration-time profile of the drug and/or key metabolites or other biomarkers thought to be related to clinical performance following administration of a product. The PK parameters estimated from the data, such as area under the curve (AUC), the maximum concentration observed for each subject or C_{max} , the timing of the maximum concentration or T_{max} , clearance rate, and half-life, etc., can inform both efficacy and safety and support dose and dosing schedule considerations. For generic drugs, the approval is often based on a PK study only, to demonstrate bioequivalence between a generic product and a licensed reference product.^[8]

In most PK studies, a simpler non-compartmental model approach is often used to derive the PK parameters for each individual subject, which generally yields comparable results as a compartmental modelling approach. However, in some situations a modeling approach is desired or needed. For example, when blood samples are collected from patients and thus are sparse or at different times across different patients or when the goal is to predict PK parameters or concentration-time profiles, a population PK model is often used to analyze the data from all subjects simultaneously. A population kinetic modeling analysis may involve the use of non-linear mixed effects models which include subject specific terms as random effects. Covariates such as body weight and age can be included in the model as well. Both Bayesian and frequentist approaches are used though frequentist methods are much more common. Bayesian approaches to population PK modeling may allow for more personalized dose regimes while still limiting the number of blood samples that have to be collected on any subject but could provide a path to developing pediatric dose recommendation.^[9]

LATE PHASE/CONFIRMATORY CLINICAL TRIALS

The role of phase 2 or proof of concept studies may vary with therapeutic area. These studies can include somewhat complex dose finding algorithms^[10] that aim to identify a dose that is safe and efficacious in treating the intended disease. With respect to study size, phase 2 studies are generally larger than in phase 1 in order to collect more safety data or/and obtain a reliable treatment effect size for future planning. Sometimes the investigational product is compared with an already approved treatment, or with

a placebo. Sometimes the phase 2 study is a randomized controlled trial.^[11] If phase 2 study results show that the investigational product may be as good as the existing treatment, or better than a placebo, it then moves into confirmatory phase that aims to confirm the safety and efficacy of the product for the intended disease for registration purposes. Phase 2 studies ought to be designed to gather data for planning an appropriate future phase 3 study with a reasonable likelihood of success. Sometimes more than one phase 2 study is needed because questions are generated after an initial phase 2 study.

Confirmatory studies are sometimes called phase 3 studies or registration studies as the results are often captured in a product label. In these phase 3 studies it is considered important to pre-specify how the results will be evaluated and how type 1 error will be controlled. Evidence that the study has adequate power to meet its objectives is also an important consideration. Statistical methods in the literature have most often been focused on the later phases of development but in recent years have provided means of combining more than one phase in a single study.

In planning a late phase study it is important to anticipate what can go wrong or plan for how some data is handled. For example, patients may want to go onto rescue medication if they fail to respond to a therapy and even if they stay in the study, how that information is included in the assessment of treatment benefit ought to be discussed in advance.^[12] In general, the interpretation of study results could be problematic if there is a high rate of missing data or a high rate of protocol deviations in the study since study results calculated using different approaches to handling missing data or dealing with protocol deviations may lead to inconsistent interpretations.^[13,14]

Randomization

The most common feature in phase 3 clinical trials is randomization. How one does randomizations and cautions over getting it done appropriately has been a common topic in the biostatistics literature and of concern in a regulatory submission. The objective of randomization in clinical trials is to balance subjects' demographic and baseline characteristics before receiving study therapies, so a sensible treatment comparison can be made at study completion. The most important advantage of randomization when properly performed is that it minimizes selection and allocation bias by balancing both known and unknown factors in the random assignment of treatments. As a result, randomization serves the basis for a statistical test of treatment effect that requires very few assumptions.

There are different types of randomization schemes.^[15] The most basic one is complete randomization (or simple randomization). Complete randomization on average achieves balance between treatment groups on both known and unknown factors. Imbalances do occur sometimes, especially in small trials and when there are many

covariates. One remedy is stratification with the use of permuted block randomization within subgroups defined by pre-specified prognostic factors. However, stratified randomization can become counterproductive when there are many prognostic factors to balance possibly resulting in a small number of patients within each stratum. Dynamic allocation has been proposed as an alternative when there are a large number of covariates to be balanced. Minimization is a type of dynamic allocation which has been used commonly, especially in oncology clinical trials.^[16] FDA would generally expect an analysis that respects the kind of randomization used in the study design so some cautions exist over the use of dynamic allocation methods.

Some of the advantages of randomization can be lost if protocol deviations or missing data disproportionately impact one treatment group and not another. If the reasons for missing data vary by treatment arm, e.g. placebo recipients drop out because of lack of efficacy and treatment recipients drop out because of side effects, there can still be some concerns in interpretability of trial outcomes.

Adaptive Randomized Designs

Adaptive randomized trial designs allow modification of trial procedures and/or statistical methods of ongoing clinical trials using accumulated data learned from interim analyses. A potential beneficial feature of adaptive design is that it may speed the development process of drug/biological products and therefore reduce costs, streamline the product development process and thereby leads to earlier availability of products.

There are numerous adaptive design features that can be applied to clinical trials including adaptive randomization, adaptive dose finding, sample size re-estimation^[17] and can include Bayesian approaches for dose escalation and dose finding. There have been many proposed adaptive design methods^[18,19] in the literature. When adaptive design protocols are submitted to a regulatory agency, how the design would generate valid and interpretable outcomes is essential. Some of the key considerations of adaptive design clinical trials are captured in 2010 FDA draft Guidance,^[20] *Adaptive Design Clinical Trials for Drugs and Biologics*. The emphasis of the FDA draft Guidance document is on adequate and well-controlled studies since that is consistent with the regulations. Though adaptive designs allow modification of design features during the course of trials, all adaptations should be planned ahead and pre-specified at the design stage. Study designs and proposed analyses will be evaluated for adequate control of type 1 error and the potential for operational biases.

Ambitious study designs that incorporate a number of adaptive features may be hard to interpret. Therefore, in therapeutic areas where high dropouts are common, or where there is heterogeneity in the patient population being studied, careful attention needs to be made to the ultimate interpretation of study results. Clinical and statistical

judgment may be factored into the evaluation of any study but with adaptive designs, simulations can be particularly useful. Simulations can be used for not only just demonstrating power and/or type 1 error control but also to generate a discussion between clinician and statistician at the planning stages. When simulations are conducted for others to examine, clear documentation and justification for what the results demonstrate are expected.

Bias can be an issue in any study, but the bias that comes because of one or more interim looks of data to modify study design is of special concern with adaptive designs. Other articles in this encyclopedia expand on the bias issues.

Companies that elect to use an adaptive design may often engage a data monitoring committee (DMC) to both monitor for safety and evaluate interim analyses.^[21] The role of DMC in adaptive design clinical trials could become more complex.

Before someone engages in planning an adaptive design, common sense ought to be that they examine whether a simpler design will suffice to demonstrate the safety and efficacy of the proposed product and/or answer scientific questions. It is in the best interest of public health to get new products to market for patients in need. However a poorly planned adaptive design is both time consuming and costly and may not bring new products to market sooner.

Bayesian Approach

Bayesian approaches can be applied to just about any phase of product development and sometimes have adaptive features though at FDA we have seen them more commonly in early phase studies. This is likely to change in the future and one would anticipate more research around Bayesian designs suitable for a regulatory submission. As noted earlier, in oncology a variant of a continual reassessment method is common in phase 1 but one may see a different type of Bayesian dose finding algorithm in phase 2. It is less common to see a Bayesian approach in late phase or confirmatory trials in drug development, though recently more have been agreed to. Type 1 error rates are not part of a classical Bayesian formulation but because a regulatory agency would be uncomfortable approving a product based on a study that came with a high potential for a type 1 error, companies still need to demonstrate, often via simulation, that type 1 error is sufficiently small and controlled. Current research in this area includes best practices for demonstrating type 1 error control for the purposes of a regulatory submission.

One of the strengths of Bayesian methods is the natural way one can combine data from multiple sources. Bayesian methods have been proposed for “extrapolation” to pediatric populations where adult data for the same indication can form an informative prior or be used in some form of Bayesian hierarchical model. Although FDA has issued a guidance for pediatric extrapolation for medical devices

including some suggestions that a Bayesian approach to combining adult and pediatric data would be appropriate,^[22] many of the principles are not unique to devices and may find their way into drug or biologic approvals.

Among the most innovative use, Bayesian methods have been used in the development of platform designs where multiple products from multiple companies are tested in the same trial and treatment arms may be added or dropped during the trial. The ISPY2 Phase 2 trial^[23] for the treatment of neoadjuvant breast cancer is one such example but more have been proposed. Each one is likely to be unique and geared to what is known about a given disease and can consider stratification of patients within the disease (e.g. using biomarkers to define patient subgroups).

Noninferiority Trials

An active-control trial is one of four kinds of concurrently controlled trials that provide evidence of effectiveness described in FDA’s regulation on adequate and well-controlled studies (21 CFR 314.126). Active-control trials often rely on non-inferiority testing. The objective of a non-inferiority trial, per FDA’s Guidance on Non-Inferiority Clinical Trials,^[24] is to show that the difference between the investigational product and active control treatment is small, small enough to allow the known effectiveness of the active control to support the conclusion that the investigational product is also effective.^[25]

Multiple Endpoints

In evaluations of an investigational product, clinical endpoints are measures in a clinical trial to reflect the effects of the product. Because of complexity of diseases, there is often interest in more than one endpoint for a study indication. For example, with a pneumococcal vaccine, there may be an immunogenicity endpoint for each of several types of pneumococcal subtypes and the goal would be the success on all such endpoints. No adjustment in type 1 error control would be made if all co-primary endpoints need to be successful. When there are many endpoints of interest in a clinical trial and success of any endpoint could be considered evidence of effectiveness, failing to adjust the assumed type 1 error for each of several possible success scenarios would result in an increasing rate of falsely concluding a therapy is efficacious when in fact it is not. Such a consideration is particularly important for regulatory decision making in adequate and well-controlled studies that serve as the primary evidence in pre-market applications. For additional discussions, see Bretz et al^[26,27] and Huque et al.^[28]

Historically Controlled Trials

Historically controlled trials are trials intended to support a comparative conclusion regarding an investigational therapy, where the ‘comparator’ is not a concurrent group

of subjects. Rather, data of the ‘comparator’ are from a prior study, studies, or possibly a registry. Therefore, one would need to have legal access to the historical data on the patient level and all the appropriate baseline covariates need to have been measured and collected. This may be a challenge. Such trials are not commonly seen in drug or biologic product development for regulatory purposes. However, they have been considered for rare diseases for which few therapeutic options exist. This kind of study could be more plausible in those rare disease settings where the natural history of the disease and its progression are well documented.

Obviously historically controlled trials don’t have the interpretative advantage of a randomized clinical trial and so one would expect them to be less common in most pre-market therapeutic settings. Propensity score methods^[29] originally developed for observational settings have been used largely in confirmatory medical device trials in an effort to account for some differences between subjects that are in a current trial versus those that come from an older study. The methods have advantages over not using propensity scores especially when one knows what covariates belong in the score but unlike randomization cannot balance for covariates that are not part of the score.

Sometimes one sees a study that is a single arm study with a pre-specified success criteria based on literature and clinical judgment. This type of study tends to be seen in those therapeutic areas in which the outcome of a control arm is thought to be well understood; e.g. when the natural course of the disease is well documented. In addition, ethical factors can weigh in. So with some rare diseases or diseases that are often fatal such as late stage cancers, it may be considered unethical or unnecessary to use a control arm. Although we have not seen this often in a drug and biological setting, perhaps a Bayesian approach that borrows some historical control information is preferable to a study that relies solely on external data to characterize the control group.

Biomarkers In Late Stage Trials

Biomarkers are used in various stages of drug development. Some are defined in terms of patients characteristics at baseline and can include prognostic markers related to disease severity or anticipated outcomes in the absence of treatment. It can also include predictive markers that identify patients who may benefit from a specific therapy.^[30]

In the academic literature, there is a definition of a surrogate endpoint that can be used to predict treatment benefit using an endpoint of primary concern.^[31] For example, improvements in HIV viral load are used in place of advancing from being HIV positive to development of AIDS related symptoms.^[32] Within a regulatory setting and defined in regulations, a surrogate endpoint is an endpoint reasonably likely to predict clinical benefit and may form the basis of accelerated approval. The two definitions are not equivalent.

Subgroups In Clinical Trials

Heterogeneity in treatment response within a single trial is a recognized outcome and regulatory submissions have to address treatment response by demographic subgroups, and possibly treatment response by region (e.g. by U.S. versus non-U.S.). The complexity of addressing this is not trivial because of possible inflation of type 1 error rate and also inadequate power to identify treatment differences.^[33,34]

Quality By Design In Clinical Trials

There is a recognition that modern Clinical Trials have become quite complex and many can fail to meet key objectives if not planned correctly.^[35] Having an eye on the study objectives throughout the planning process is helpful and statisticians can play a role in developing study design options that lead to more interpretable outcomes. For example, by selecting subjects more likely to comply with directions (“enriching for compliers”), we may have fewer missing data points. Getting investigators to work together, and standardizing more subjective endpoints can lead to a cleaner result. Statisticians can also help with algorithms to monitor trials in order to identify problems (e.g. an unforeseen rise in a particular safety concern).^[36] Statisticians need to be engaged in all aspects leading up to a clinical trial including planning, conduct and analysis.

Bioequivalence And Biosimilarity

In academic training the emphasis is on clinical trials designed to assess treatment differences or superiority of one treatment over another. In a regulatory environment while there is always a need for superiority trials, there is also a need for demonstrating two products are sufficiently similar. For generic drugs the term is bioequivalence and for a biologic, the term is biosimilarity.^[37,38] There is a well-established literature on bioequivalence but a more limited literature on biosimilars.^[39]

Vaccines For Preventing Disease

The Center for Biologics Evaluation and Research (CBER) at FDA regulates vaccine license applications and works with other agencies to monitor vaccine efficacy and safety in post-licensure. Even when a new vaccine is compared to a placebo control, it is often not adequate to demonstrate that the vaccine is superior to a placebo, but a more stringent criteria needs to be set. Vaccine recipients are often healthy and in the context of balancing risk and benefit, one may ask that the vaccine demonstrate that it can prevent at least a pre-specified percentage of cases of the disease. This would lead to a super-superiority hypothesis of primary concern.^[40,41] In addition to clinical efficacy studies, vaccine lot to lot consistency usually

needs to be demonstrated in a clinical study using immunogenicity endpoints to assess equivalence among three consecutive lots.

A particular topic of interest in the development of a novel vaccine is a biomarker that can be used to determine who is or is not protected by the vaccine, a correlate of protection. Study designs to establish the existence of a correlate of protection at individual or population level are of great interest in a regulatory setting.^[42–44] Immunobridging methods to assess vaccine efficacy in a population different from the population in which the correlate of protection is established may also present challenges. A few such studies have been submitted to FDA.

Large Simple Safety Trials

The typical premarket assessment of a novel product involves a detailed assessment of any observed adverse events. Some caution is needed in separating events associated with the disease being treated and events that may be attributable to the drug investigated in the trial. If the events are rare but it is unclear if a signal, though rare, may exist, companies may be asked to conduct a large simple safety trial. The concerns over evaluating some of these have been documented particularly in the context of cardiovascular outcome trials^[45] and new methods have been proposed.^[46] Because safety is of paramount concern in vaccines, we have also seen an efficacy study embedded in a larger safety study (e.g. REST trial).^[47] They are often called ‘simple’ largely because they focus on a limited amount of safety data collected on each subject in the trial.

Benefit-Risk

Regulators and companies are increasingly being asked to consider the balance of risks and benefits of medical products. This has led to a formal literature including a recent book by Qi Jiang et al.^[48] The more quantitative approaches including Bayesian methods are likely to provide opportunities for formal statistical approaches that capture uncertainty in the various pieces of evidence contributing to the assessment.

POSTMARKET SURVEILLANCE

Once a product is approved or licensed, FDA and companies often engage in collecting additional post-market data. Most premarket clinical trials only provide a preliminary evaluation of product safety and may fail to capture rare but serious adverse events. There are two very common types of surveillance.

FDA provides for voluntary reporting of suspected adverse reactions to a drug or biologic or possibly a reaction when two or more products are taken together. Passive surveillance refers to the idea that only complaints are

registered and we recognize that while we see complaints we may not know how many units of the product were dispensed. This has led to a number of statistical algorithms focused on data mining in passive surveillance systems. Empirical Bayesian methods^[49] and more recent Likelihood methods^[50] are designed to find unanticipated safety signals that are then further investigated using other data sources.

Active surveillance refers to the idea that FDA and others may elect to pursue adverse events using a system that provides numerators and denominators and is studied in a prospective manner. The Vaccine Safety Datalink is among the oldest such systems (since 1991) and methods such as Rapid Cycle Analysis^[51] have been used to successfully study a pre-specified potential safety concern using data from electronic health records. FDA engages in joint activities with other federal agencies and some interesting statistical advances have come of that. The biggest FDA-sponsored post-market active surveillance system to date is the Sentinel system and the reader is encouraged to visit the Sentinel system website (<http://www.sentinel-system.org>). Even though Sentinel is considered an active surveillance system, it is often used to take a look a retrospective look at insurance claim data and/or electronic health records with millions of individuals in the system. Claims data are often updated over a period of months because of claims being settled and then recorded in the dataset. One may need to account for a lag in reporting of relevant data in any model that analyzes data as rapidly as possible. This can be a challenge with evaluating safety of new products and/or seasonal influenza vaccines that are reformulated each year.^[52] Claims data can also have limitations since one may track what procedures have been billed for but sometimes a final diagnosis may not be recorded. When combining claims data from multiple providers, one needs methods that work in a distributed system since the detailed patient level data needs to stay behind a firewall.^[53]

ESSENTIALS OUTSIDE OF CLINICAL DATA

Regulatory agencies regulate the entire product and look at more than just data from one or more clinical trials. This can include evaluating lab assays that are critical to product evaluation and manufacture. For example, the release and stability assays and their specifications for all quality attributes of a drug or biological product must be established prior to licensure. Many changes related to product manufacture and release test may occur at different stages of the product life cycle. For example, a biological product may be produced in a pilot scale during the product’s development but need to be scaled up to produce millions of doses annually before licensure. Potency assays may change post licensure as technology advances, which may or may not require change of product specifications. Manufacturing

site, with or without scale-up, or testing site may change. Critical manufacturing materials, critical test reagents, or instrument/equipment may need to be replaced. FDA is regulating the product for the purpose of protecting public health and modifications to manufacture and acceptance criteria may evolve from early testing to later phases and in post-market. Comparability/bridging before and after each change needs to be evaluated to ensure the product remains efficacious and safe as the clinical lots used in the clinical trials to demonstrate efficacy and safety of the product. Statistical contributions in this area are substantive (see FDA Guidance on process validation).^[54]

Laboratory assays are essential in the support of clinical development of a product too. For generic drugs, approval is often based on bioavailability/bioequivalence studies which evaluate the kinetic profile of drug concentrations measured by assays. For new drugs or biologics, when a clinical efficacy trial is unfeasible, unethical (e.g., anthrax, pandemic flu, Ebola), or takes too long to conduct, biomarker data will be the key evidence supporting efficacy under accelerated approval or animal rule pathway. For therapeutic biologics, an immunogenicity assay is also an important tool for safety evaluation (see FDA draft Guidance on immunogenicity assay).^[55] For vaccines, serology assays used to measure vaccine induced immune response are key for developing a vaccine and interpreting modifications of manufacturing. Selection of vaccine dose, schedule, or formulation and lot consistency studies are usually based on immunogenicity. When there is an established correlate of protection, efficacy of a vaccine may be demonstrated by immunogenicity studies. Therefore, assays play a critical role in the preclinical and clinical development programs of many therapeutic and preventive products. The validation of bioanalytical assays used for quantifying analytes in complex biological matrix involves issues different from assays used for testing product quality, for example, the need of using incurred samples (see FDA draft Guidance on bioanalytical method validation),^[56] and thus presents different statistical challenges in the design and analysis of validation studies.

FDA engages many stakeholders in this setting. In addition to FDA guidance, FDA staff participate in many external organizations to further best practices. For example, U.S. Pharmacopeia is an organization that develops many guidelines^[57–60] associated with bioassays for drug and biologic development and assessment. Physicians may elect to recommend a drug for a patient based on the results of a laboratory test and the Clinical Laboratory Standards Institute (CLSI) publishes guidelines that are used in the in vitro diagnostics industry and are the result of an agency and industry working group; multiple CLSI guidelines have been recognized by FDA.^[61] Guidelines may address the development of an assay analysis method by discussing issues in model selection, transformation, weighting, and calculation of potency, etc. and the performance of an assay by recommending designs and statistical analysis

methods to assess precision, accuracy, linearity, specificity, robustness, stability and so on. ICH Q2(R1)^[62] provides definitions to assay validation parameters recognized by drug and biologic regulators. Statistical methods for evaluating assay performance have been evolving over the recent years, and have been or are being updated in some guidances. For example, equivalence approach is now well recognized as the appropriate way for testing parallelism, a fundamental assumption of dilution assays, and for testing assay comparability. How to set equivalence margins, however, remains a difficult issue for many assays. Differences in parameter definitions and statistical approaches may still exist across guidances by different organizations or from different countries, for different types of assays, and for different uses of assays. There are plenty opportunities for new statistical ideas in this area.

TOPICS LIKELY TO GAIN MORE PROMINENCE

Precision Medicine

Precision medicine is and will continue to challenge statisticians. We are still far from tailoring a treatment to an individual but we are getting closer to recommendations for groups of individuals. Many groups in a study usually mean fewer subjects within any given group. Topics in this vein would include adaptive enrichment designs,^[63] the evaluation of companion and complementary diagnostics (diagnostics that provide useful information in the selection of therapies for patients).^[64]

Real World Evidence

Everyone is aware of the limitations of clinical trials relative to what happens once a drug is approved. Other kinds of studies could help inform the use of a drug. This can include alternative designs, e.g. a pragmatic trial^[65] that evaluates real world use of a clinical product for a broad group of subjects. This can sometimes include a group or cluster randomized trial in which e.g. a nursing home or a medical practice is assigned a treatment group rather than individual subjects (see Hayes et al^[66] and special issue in Clinical Trials October 2015). Registries and/or large databases may also be used to inform efficacy as well as safety. The methodology in this arena is continuing to be developed as is the context for the use of such studies in a regulatory setting such as FDA.

Science Of Patient Input

Regulatory agencies are listening to patient groups and would like to have formal assessments of patient reported outcomes (PRO)^[67] and patient preference information (PPI).^[68,69] Methodology normally seen in psychometrics and in the survey world (e.g. questionnaire

development) will likely influence how one develops a PRO and the methodology for eliciting patient preferences may be influenced by marketing research methodology.

CONCLUSIONS

As the discussion presented indicates, statisticians and statistical methods have a role to play in just about every phase of pharmaceutical development and assessments, whether by a company or a regulatory agency such as FDA. The role of statisticians in regulation in particular is often downplayed and too often trivialized as “guardians of a p-value”. Approval of medical products has become very complex and often information from multiple sources needs to be brought together to form the totality of evidence. Statisticians, with their quantitative training and their understanding of evidence synthesis and quantitative decision making will have an increasing role in a regulatory setting. We have highlighted more traditional activities but also tried to note some new methods likely to have increased visibility in a regulatory environment. Because the theme of this article is regulatory statistics we have not mentioned the substantial literature related to drug development from a pharmaceutical company perspective.

Release Targets

Greg C. G. Wei

Pfizer Global Research and Development, Groton, Connecticut, U.S.A.

Abstract

This entry discusses how manufacturers of pharmaceutical drugs need to set the in-house specification on the initial potency high enough such that a batch that satisfies this specification at time zero will meet the LRL with high certainty, a specification standard known as release target.

INTRODUCTION

Manufacturers of drug products must demonstrate that their products meet with United States Pharmacopeia specifications before the products can be released for sale. One of the important specifications is the low registered limit (LRL) on drug's potency. After a drug product is manufactured, the natural degradation process gradually reduces the drug's potency. A drug's potency must remain above the LRL at the end of its registered shelf life. An important factor in the determination of the potency at the end of shelf life is the drug's potency at time zero, or the initial potency. Manufacturers need to set the in-house specification on the initial potency high enough such that a batch that satisfies this specification at time zero will meet the LRL with high certainty. This in-house specification is called the release limits (RLs) or the release targets. A typical scenario is illustrated in Fig. 1.

Some statistical approaches have been developed to determine the RLs of the initial drug potency. Allen et al.^[1] proposed a simple method for calculating the RLs. Wei^[2] suggested a similar but more statistically justifiable approach. Shao and Chow^[3] adopted a Bayesian decision theory approach to construct the RLs. This article will only describe the methods by Allen et al. and Wei. The Bayesian method by Shao and Chow will not be discussed in this article due to its technical complexity.

ALLEN ET AL. METHOD

The idea of their approach is very intuitive. To ensure potency of the shelf life above the registration limit, the RL was made equal to the registration limit plus a "buffer." The buffer consists of the potency decrease over the shelf life, the variability associated with the rate of decrease, and the variability of the assay. These quantities are estimated from stability studies using linear regression analysis.

Case I: Product with No Degradation

The expression of the RL is shown in the following equation:

$$RL = LRL + t \times \frac{S}{\sqrt{n}}$$

where RL is the release limit; LRL is the lower registration limit; S is the assay standard deviation; DF is the degrees of freedom; t is the 95% confidence (one-sided) t value with DF; and n is the number of replicate assays used for batch release.

Case II: Product with Degradation

For products whose potency decrease over the shelf life due to degradation process, RL can be calculated as follows:

$$RL = LRL + bT + t \sqrt{S_T^2 + \frac{S^2}{n}}$$

where b is the average degradation rate; T is the shelf life; and S_T is the standard error of bT .

The degrees of freedom used to determine t can be calculated by the Satterthwaite approximation.

Case III: Product Requiring Reconstitution Prior to Use

Some products must be reconstituted before use. The potency decrease due to reconstitution and its variability must be taken into account in RL calculation. RL can be calculated as follows:

$$RL = LRL + bT + rT + t \sqrt{S_T^2 + S_R^2 + \frac{S^2}{n}}$$

where r is the average degradation rate of the reconstituted solution; and S_R is the standard error of the average degradation rate of the reconstituted solution.

Fig. 1 Release limit of drug potency

The degrees of freedom used to determine t can be calculated by the Satterthwaite approximation.

CONDITIONAL AND UNCONDITIONAL METHODS

Allen et al.'s method for RL determination is very appealing due to simplicity and intuitiveness. However, it lacks a rigorous statistical justification. Wei^[2] proposed a more justifiable statistical derivation. His method is briefly described here.

Decision Rules

First, let us define two types of RLs in the following decision rules, expressing each one in a probability statement. The basic idea is that RL should be set at a value such that the probability of failing LRL at the end of shelf life is controlled.

Conditional Rule

Let y_{i0} be the observed sample average of time-zero potency. Find an RL such that if $y_{i0} \geq \text{RL}$, then

$$P(\text{Lower 95\% confidence interval (CI) of true potency at time } T < \text{LRL} | y_{i0}) \leq \alpha$$

This rule defines RL as a value such that if the potency measurement at time zero is above this value, then the probability of failure for this batch at time T will not be more than α .

Unconditional Rule

Find RL such that

$$P(\text{Lower 95\% CI of true potency at time } T < \text{LRL} | \text{RL} \leq y_{i0} \leq M) \leq \alpha$$

This rule defines RL as a value such that as long as the potency measurement at time zero is above this value and below the upper limit M , the probability of failure will not be more than α . The RLs defined in the conditional and the unconditional rules both control the chance of failure at a given α . However, the two rules have different meanings. The RLs based on the conditional rule, denoted by RL(C), keeps the chance of failure for *each* released batch under α , whereas the RLs based on the unconditional rule, denoted by RL(UC), keeps the chance of failure for *all* future released batches under α .

Release Limits Based on the Conditional Rule

Let the observed potency follows the following model with parameters b , σ_a^2 , σ_β^2 , and σ_e^2 , then for k th replicate from i th batch at time t ,

$$y_{ik} = \mu + \alpha_i + (b + \beta_i)t + e_{ik}, \\ t = 0, t_1, t_2, \dots, T, \quad k = 1, 2, \dots, n_i$$

where y_{ik} is the assayed potency of k th replicate, i th batch, at time t ; μ is the mean batch potency at time zero; α_i is the random batch effect on potency at time zero, $\alpha_i \sim N(0, \sigma_a^2)$; b is the average potency change rate per time unit; β_i is the random batch effect on slope, $\beta_i \sim N(0, \sigma_\beta^2)$; t is the

sampling time; e_{itk} is the total random assay error, $e_{itk} \sim N(0, \sigma_e^2)$; α_i and β_i are independent; and (α_i, β_i) and e_{itk} are independent.

The same model can also be expressed as

$$y_{itk} = \mu_i + b_i t + e_{itk}, \quad t = 0, t_1, t_2, \dots, T, \quad k = 1, 2, \dots, n_i$$

where $\mu_i = \mu + \alpha_i$; and $b_i = b + \beta_i$.

Having observed the sample average of n_0 assay values at time zero, y_{i0} , the future observed assay value at time t follows a new model below,

$$y_{itk}^* = y_{i0} + \eta_i + (b + \beta)_i t + e_{itk}, \quad t = t_1, t_2, \dots, T, \quad k = 1, \dots, n_i \quad (1)$$

where $\eta_i \sim N(0, \sigma_e^2/n_0)$.

Let

$$\begin{aligned} Y_{it} &= \begin{pmatrix} y_{it1} \\ y_{it2} \\ \vdots \\ y_{itn_i} \end{pmatrix}, & X_{1t} &= \begin{pmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{pmatrix}, \\ X_{2t} &= \begin{pmatrix} t \\ t \\ \vdots \\ t \end{pmatrix}, & E_{it} &= \begin{pmatrix} e_{it1} \\ e_{it2} \\ \vdots \\ e_{itn_i} \end{pmatrix}, \\ Y_i &= \begin{pmatrix} Y_{i0} \\ Y_{i1} \\ \vdots \\ Y_{iT} \end{pmatrix}, & X_1 &= \begin{pmatrix} X_{10} \\ X_{11} \\ \vdots \\ X_{1T} \end{pmatrix}, \\ X_2 &= \begin{pmatrix} X_{20} \\ X_{21} \\ \vdots \\ X_{2T} \end{pmatrix}, & E_i &= \begin{pmatrix} E_{i0} \\ E_{i1} \\ \vdots \\ E_{iT} \end{pmatrix} \end{aligned}$$

also

$$\begin{aligned} Y_i^* &= \begin{pmatrix} Y_{i1}^* \\ Y_{i2}^* \\ \vdots \\ Y_{iT}^* \end{pmatrix}, & X_1^* &= \begin{pmatrix} X_{11}^* \\ X_{12}^* \\ \vdots \\ X_{1T}^* \end{pmatrix}, \\ X_2^* &= \begin{pmatrix} X_{21}^* \\ X_{22}^* \\ \vdots \\ X_{2T}^* \end{pmatrix}, & E_i^* &= \begin{pmatrix} E_{i1}^* \\ E_{i2}^* \\ \vdots \\ E_{iT}^* \end{pmatrix} \end{aligned}$$

The model 1 in vector form becomes

$$Y_i^* = (X_1^* X_2^*) \begin{pmatrix} y_{i0} \\ b \end{pmatrix} + X_1^* \eta_i + X_2^* \beta_i + E_i^*$$

Now the point estimate of potency and its variance at time T under the new model can be calculated as

$$\begin{aligned} \hat{y}_{iT}^* &= y_{i0} + \hat{b}_i T \\ \text{Var}(\hat{y}_{iT}^*) &= T^2 \text{Var}(\hat{b}_i) = T^2 (X_2^{*T} X_2^*)^{-2} X_2^{*T} \Sigma X_2^* \\ &= T^2 \left[\sigma_\beta^2 + (X_2^{*T} X_2^*)^{-1} \sigma_e^2 \left(1 + \frac{N}{n_0} \right) \right] \end{aligned}$$

where $N = n_{i1} + n_{i2} + \dots + n_{iT}$.

To control the probability of failure for this batch, it is sufficient to control the probability that the 95% lower CI for the mean potency at time t will be below LRL under certain level (say α). It is clear that this probability is a decreasing function in y_{i0} .

$$P(\hat{y}_{iT} - z_{0.05} \sqrt{\text{Var}(\hat{y}_{iT})} < \text{LRL} | y_{i0})$$

RL is the minimum value of y_{i0} such as

$$P(\hat{y}_{iT} - z_{0.05} \sqrt{\text{Var}(\hat{y}_{iT})} < \text{LRL} | y_{i0}) \leq \alpha$$

In fact, the solution for RL can be expressed as

$$\begin{aligned} \text{RL}(C) &= \text{LRL} + bT + (z_\alpha + z_{0.05})T \\ &\quad \times \sqrt{\sigma_\beta^2 + (X_2^{*T} X_2^*)^{-1} \sigma_e^2 \left(1 + \frac{N}{n_0} \right)} \end{aligned}$$

when samples are only drawn at time zero and the end of the study.

The above expression is reduced to

$$\text{RL}(C) = \text{LRL} + bT + (z_\alpha + z_{0.05}) \times \sqrt{\sigma_\beta^2 T^2 + \sigma_e^2 \left(\frac{1}{nT} + \frac{1}{n_0} \right)}$$

Notice the similarity between the above expression and the expression in Case II of Allen et al. method. The $\text{RL}(C)$ is batch-specific. For each batch, y_{i0} will be obtained and compared to $\text{RL}(C)$ to decide whether the batch can be released. For every batch released in such a way, the probability of failure at time T is controlled. This method does not utilize any prior information about distribution of time-zero potency among batches.

Release Limits Based on the Unconditional Rule

Now suppose the distribution of time-zero potency among batches is known. Recall model

$$y_{ik} = \mu_i + b_i t + e_{ik}, \quad t = 0, t_1, t_2, \dots, T, \quad k = 1, 2, \dots, n_i$$

Use the same vector notation as above and let $X = (X_1 X_2)$. Then the lower 95% CI for the true potency at time T is Lower C for true potency at time

$$T = \hat{y}_{iT} - z_{0.05} \sqrt{\text{var}(\hat{y}_{iT})}$$

Because the lower 95% CI for the true potency at time T follows a normal distribution as can be seen from the above expression, the probability of failure at time T shown below can therefore be calculated.

$$P(95\% \text{ lower CI of true potency at time } T < \text{LRL})$$

Because the estimated time-zero potency is negatively correlated with the predicted potency at time T , the probability of failure at time T is negatively associated with the RLs at time zero. The basic idea is that for those batches which pass the RLs, the probability of failure at time T will be under an allowable value. The RL(UC) can then be solved from the following inequality, and $\bar{y}_{i0}$ is the sample mean assay value,

$$P(95\% \text{ lower CI of true potency at time } T < \text{LRL} | \text{RL(UC)} \leq y_{i0} \leq M) \leq \alpha \quad (2)$$

or

$$P\left(\hat{y}_{iT} - z_{0.05} \sqrt{\text{var}(\hat{y}_{iT})} < \text{LRL} | \text{RL(UC)} \leq y_{i0} \leq M\right) = \frac{P\left(\hat{y}_{iT} - z_{0.05} \sqrt{\text{var}(\hat{y}_{iT})} < \text{LRL} \cap \text{RL(UC)} \leq y_{i0} \leq M\right)}{P(\text{RL(UC)} \leq y_{i0} \leq M)} \leq \alpha$$

Under normality, RL(UC) can then be solved using the joint distribution of y_{i0} and the predicted y_{iT} as given below.

$$\begin{pmatrix} y_{i0} \\ \hat{y}_{iT} - z_{0.05} \sqrt{\text{var}(\hat{y}_{iT})} \end{pmatrix} \sim N\left(\begin{pmatrix} \mu \\ \mu + bT - z_{0.05} \sqrt{\text{var}(\hat{y}_{iT})} \end{pmatrix}, \text{cov}\begin{pmatrix} y_{i0} \\ \hat{y}_{iT} \end{pmatrix}\right)$$

and

$$\text{var}(y_{i0}) = \sigma_\alpha^2 + \frac{\sigma_e^2}{n_0}$$

$$\text{cov}(y_{i0}, \hat{y}_{iT}) = \frac{1}{n_0} (1'_{n_0}, 0'_{n_1}, \dots, 0'_{n_T}) \sum X(X'X)^{-1} \begin{pmatrix} 1 \\ T \end{pmatrix}$$

Then the minimum value for RL(UC) which satisfies the inequality 2 can be easily found using a numerical search routine.

Expected Loss Function Approach

RL(UC) keeps probability of failure for all future batches under α . A smaller α means a fewer number of batches fail LRL at time T , but a smaller α will also result in a larger number of batches fail to be released. A failed batch at time zero or time T will both be a financial loss to the manufacturer. Therefore, an alternative way to determine RL(UC) is to find one which minimizes the total expected loss provided that the financial loss due to failing a batch at time zero and time T are known.

Suppose

Financial loss due to failing a batch at time 0 = L_0 .

Financial loss due to failing a batch at time T = L_T .

Then

Expected Loss = $L_0 P(\text{a batch failed at time 0}) + L_T P(\text{a batch failed at time } T)$

$$\text{Expected Loss} = L_0 P(y_{i0} < \text{RL(UC)}) + L_T P(\text{RL(UC)} \leq y_{i0} \leq M \cap \hat{y}_{iT} < \text{LRL})$$

RL(UC) that minimizes the above function can then be found using a numerical search routine.

All three methods described in this section require prior knowledge about certain parameters. For the conditional method, they are b , σ_β^2 , and σ_e^2 , and μ , b , σ_α^2 , σ_β^2 , and σ_e^2 for the unconditional method. In practice, these knowledge can be obtained from different sources such as assay validation studies, previous stability studies, and published results.

CONCLUSION

The Allen et al. method is very appealing to practitioners for its simplicity and intuitiveness. However, their method was not established on a justifiable statistical argument. Having this drawback, the property of their RL is not clear. Nonetheless, the performance of their method may still be satisfactory in practice.

The three methods proposed by Wei were derived from a probability argument of failure rate control. The conditional method is the easiest one to calculate and requires the least information. It should be used in the situation where no prior knowledge about the distribution of batch potency at time zero. The unconditional method is an improvement over the conditional method at the expense of availability of prior knowledge about the distribution of batch potency at time 0. However, these two methods both focus on controlling failure rate of batch at time T , they do not account for cost due to batch rejection at time zero. The loss function method minimizes the expected loss due to batch failure at time 0 and T when cost ratio is available. In practice, which method to use will depend on the availability

of the required information. The estimated RL should be treated as an important component in the whole process of RL determination along with other deciding factors such as production capability and other practical issues.

Reliability

Valentin Rousson and Theo Gasser

University of Zurich, Zurich, Switzerland

Abstract

This entry reviews some issues of reliability for continuous measurements with a focus on three kinds of reliability: intrarater, interrater, and test-retest reliability.

INTRODUCTION

Classical statistical analysis usually assumes that data are measured without error. Yet even in exact sciences such as physics, data are recorded with errors, and these are even more important when data are the result of ratings. One usually distinguishes between two kinds of measurement error: systematic error (or bias) and random error (or variability). The first one arises when the “measuring instrument,” such as a rater, gives values that are systematically too large, or systematically too low, compared to the “truth.” These errors are especially annoying when data are obtained from different sources (such as different raters) with a varying amount of systematic error. Random errors are attributable to the fact that an instrument does not exactly give twice the same value when twice measuring the same thing. Reasons for this may be slight changes in the external conditions, for example. Random errors lead to underestimating correlations between variables, and more generally make it more difficult to obtain significant results. Thus, before introducing new techniques or rating scales, it is advisable to perform an analysis of measurement error, and such an analysis is called a *reliability analysis*.

Reliability is sometimes confounded with validity. Whereas reliability is about measurement error, validity refers to the appropriateness, meaningfulness, and usefulness of what is being measured. For example, an IQ test is said to be reliable if it twice provides similar results when applied twice to the same subject. On the other hand, an IQ test is said to be valid if it measures what is meant by intelligence. Validity is especially important in social sciences where the variables of interest, such as intelligence or satisfaction, may not be directly measured (they are referred to as “latent” variables). In natural sciences, one usually measures more “concrete” variables, and the problem of validity is less important. Interestingly enough, both reliability and validity can be improved by the building of “components,” i.e., by combining several variables together (as performed in an IQ test). But while validity may be improved by considering relevant variables that are

not necessarily correlated with each other, the reliability of a component will be generally higher when the combined variables are correlated, as shown below.

Another concept related to reliability is agreement. For categorical data, the agreement between two measuring instruments is usually defined as the percentage of times that the same value is achieved. For continuous data, one is interested in differences between measurements provided by two instruments (in the actual scale of the data), and hence agreement measures “accuracy.” By way of contrast, reliability informs us about the ability of the instruments to differentiate among the entities measured. Thus, reliability will depend on the population of entities considered, much like a correlation coefficient, such that the more heterogeneous the population, the higher the reliability. Agreement and reliability might therefore provide a very different picture of the situation.

In this entry, we review some issues of reliability for continuous measurements. We shall focus on three kinds of reliability: intrarater, interrater, and test-retest reliability. The standard method for assessing reliability in this context is intraclass correlation. But we shall see that different kinds of intraclass correlation coefficients should be used depending on the situation. The key difference will be the treatment of the systematic error that might or might not be a deficiency of the measuring procedure.

SOME CONSEQUENCES OF MEASUREMENT ERROR

Before discussing in detail how to assess reliability, let us illustrate some effects of measurement error on scientific research by first considering the classical two-sample problem. Let X and Y be normally distributed variables with expectations μ_X and μ_Y and with common variance σ^2 . The test statistic is given by $t = (n_X n_Y / (n_X + n_Y))^{1/2} (\bar{X} - \bar{Y}) / s$, where $\bar{X}$ and $\bar{Y}$ are the sample means of data in both groups, s^2 is an estimate of σ^2 , and n_X and n_Y denote sample sizes. If data are recorded with errors, they are actually sampled from $\tilde{X} = X + \epsilon_X$ and $\tilde{Y} = Y + \epsilon_Y$, where ϵ_X and

ϵ_r denote measurement errors. In what follows, we shall assume ϵ_X and ϵ_r to be normally distributed with expectation v_X and v_r , and with common variance τ^2 , and to be independent from each other and from X and Y . Thus variables $\tilde{X}$ and $\tilde{Y}$ are normally distributed with expectations $\mu_X + v_X$ and $\mu_Y + v_r$ and with common variance $\sigma^2 + \tau^2$.

Quantities v_X and v_r represent the amount of systematic error. For example, if v_X is larger than 0, data in the first group will be on average too large. The numerator of the test statistic is hence an estimate of $\mu_X - \mu_Y + v_X - v_r$, instead of $\mu_X - \mu_Y$. Thus, systematic errors are annoying only if v_X differs from v_r (i.e., if we have a “differential bias”). In this case, the numerator of t will be too large (if $v_X > v_r$), or too low (if $v_X < v_r$), and this will result in an invalid test.

On the other hand, the variance τ^2 of measurement errors represents the amount of random error in the data (which is taken equal in both groups in this example). Thus, the denominator of the test statistic is an estimate of $\sigma^2 + \tau^2$, instead of σ^2 , such that the larger τ^2 , the smaller the test statistic. Data recorded with random errors lead therefore to fewer significant results.

In regression, random errors do not only lead to a loss of power for the statistical tests, but also to a systematic underestimation of the strength of the association between the variables. To see this, let us consider data sampled from a pair of variables (X, Y) with marginal variances τ_X^2 and τ_Y^2 and with covariance σ_{XY} . The sample correlation $r_{XY} = s_{XY}/(s_X s_Y)$ is an estimate of the true correlation $\sigma_{XY}/(\sigma_X \sigma_Y)$, where s_X^2 and s_Y^2 denote sample variances and s_{XY} sample covariance. Again, in case of measurement errors, data are actually sampled from $(\tilde{X}, \tilde{Y}) = (X + \epsilon_X, Y + \epsilon_r)$ instead of (X, Y) . Let us assume that measurement errors ϵ_X and ϵ_r have expectation 0 and variances τ_X^2 and τ_r^2 , respectively. Then the covariance of $\tilde{X}$ and $\tilde{Y}$ is given by

$$\begin{aligned} \text{Cov}(\tilde{X}, \tilde{Y}) &= \text{Cov}(X, Y) + \text{Cov}(X, \epsilon_r) + \text{Cov}(\epsilon_X, Y) \\ &\quad + \text{Cov}(\epsilon_X, \epsilon_r) \end{aligned}$$

If measurement errors are independent from each other, as well as from X and Y (which is a reasonable assumption), the covariance of $\tilde{X}$ and $\tilde{Y}$ is equal to the covariance of X and Y , such that the numerator of r_{XY} is still an unbiased estimate of σ_{XY} . On the other hand, sample variances estimate $\tau_X^2 + \tau_X^2$ and $\sigma_Y^2 + \tau_r^2$, and have a positive bias as estimates of τ_X^2 and τ_r^2 . As a consequence, the denominator of r_{XY} will be too large, and the sample correlation will underestimate the true correlation, even for large sample size. Such underestimated correlations are referred to as “attenuated correlations.” This phenomenon is partly responsible for the low correlations sometimes found in the social sciences, when larger ones are expected.

For similar reasons, estimates of the slope of a regression line obtained from data where the explanatory variable is recorded with error will be systematically too small. This phenomenon is sometimes referred to as the “regression dilution bias.” For an interesting example, the reader

is referred to MacMahon et al.^[1] In this study, the authors consider the association between diastolic blood pressure (DBP) with the incidence of stroke and of coronary heart disease. They note that previous analyses were carried out with DBP measured at “baseline,” which is subject to a lot of random fluctuations, leading to underestimating the true association above. They consider instead a variable called “usual DBP,” defined as the average blood pressure of an individual over several years, and they obtain slopes about 60% steeper.

DIFFERENT ASPECTS OF RELIABILITY

A reliability analysis uses repeated measurements of a variable Y . In the most common and simplest case, a random sample of n entities with each d repeated measurements is considered (this is the case of “balanced data”). In what follows, we shall denote by Y_{ij} the j th measurement made on the i th entity (for $i = 1, \dots, n$ and $j = 1, \dots, d$). When measurements are the result of ratings made on subjects performing a given task, three aspects of reliability are usually of interest: intrarater, interrater, and test–retest reliability. For intrarater data, the d measurements refer to d ratings of a same rater, while for interrater data, they are ratings of d different raters. Thus, in the former case, only one rater is needed and Y_{ij} denotes the j th measurement made by this rater on the i th subject. In the latter case, d raters are needed and Y_{ij} denotes the measurement made by the j th rater on the i th subject. Finally, in a test–retest situation, each subject should perform the task d times and Y_{ij} denotes the result of the j th trial made by the i th subject. The same three concepts may be found in other kinds of reliability studies, even if the terminology may sometimes be different. Let us, as an example, consider measurements of laboratory parameters from blood sample, performed via some instruments. The equivalent of intrarater reliability will then be the analysis of repeated measurements made on a same blood sample by a given instrument and the equivalent of interrater reliability will be the analysis of measurements by different instruments on this sample. Finally, test–retest reliability will be the analysis of measurements made on different samples from a same subject (where the subject could be measured once a week, for example). Note that when the variable to be measured varies fast in time, intrarater and interrater reliability are sometimes confounded with test–retest reliability (e.g., this may arise for blood pressure).

We shall illustrate our point with a real example. Largo et al.^[2] introduced a test battery to study the development of neuromotor functions in children and adolescents. The test battery consists of various finemotor tasks for which the time needed to complete them is recorded with a watch (or “rated” because time has, in this case, a clear subjective component). Evidently, a good reliability of such a test battery is a prerequisite for its clinical and scientific

usefulness, and hence data were collected to assess intrarater, interrater, and test–retest reliability. In what follows, intra- and interrater reliability are derived from a sample of $n = 30$ children. Each child was rated once by a first rater (in what follows, Rater 1), and twice by a second rater (Rater 2) from videotape. The two ratings of Rater 2 were performed within 8 weeks. Test–retest reliability is derived from a sample of $n = 22$ children, who performed the tasks twice 1 week apart. For all three kinds of reliability, hence we have $d = 2$.

An analysis of reliability starts with scatter plots (and other exploratory statistics) to identify peculiar patterns. As stated in the “Introduction” section, we distinguish between two kinds of discrepancy among repeated measurements. Systematic error refers to those differences that are systematically in the same direction. Random errors refer to differences that do not lie predominantly in the same direction. Fig. 1 shows intrarater, interrater, and test–retest data for one of the tasks of the test battery. While intrarater data exhibit practically no systematic error and low random error (all but one point are pretty well aligned on the identity line), there is a clear systematic error for both interrater and test–retest data. For interrater data, Rater 2 rated systematically lower than Rater 1. This is undoubtedly a failure in reliability because it indicates a lack of training or standardization. For test–retest data, the second attempt of a child was systematically better than

the first one. However, this systematic error is attributed to a learning effect, which is a natural phenomenon and not a defect of the test battery. This example shows that the systematic error should be treated differently according to the situation. This will be the subject of the section “Assessing Intrarater, Interrater, and Test–Retest Reliability.”

CONCORDANCE CORRELATION

From a bivariate sample of continuous repeated measurements as described in the previous section, reliability is often evaluated by using either Pearson (or Spearman) correlation, a paired t -test, or tests on the intercept and the slope of the least-squares regression line, to check whether they are equal to 0 and 1, respectively. Figs. 1–3 in Lin^[3] accurately illustrate why these three approaches are not appropriate to assess reliability. A perfect reliability is achieved if reliability data, as those in Fig. 1, lie all on the identity line. Thus, a high correlation does not always imply a high reliability. For example, a Pearson correlation of 1 just means that the data are perfectly aligned, but not necessarily on the identity line. In particular, it is not possible to detect a systematic error using correlation. On the other hand, the null hypothesis of a paired t -test and of tests on the coefficients of the regression line do not involve random errors at all.

Fig. 1 Scatter plots of reliability data for the timed performance (in seconds) of some neuromotor task: (a and b) interrater data, (c) intrarater data, (d) test–retest data. Identity line is plotted as reference

Let Y_1 and Y_2 be two repeated measurements of a continuous variable Y . As a perfect reliability is achieved if and only if $E[(Y_1 - Y_2)^2] = 0$, Lin^[3] proposes to use this quantity for assessing reliability. If μ_1 and μ_2 denote means, and σ_1^2 and σ_2^2 denote variances of Y_1 and Y_2 , respectively, and if ρ denotes the correlation between Y_1 and Y_2 , we have

$$E[(Y_1 - Y_2)^2] = (\mu_1 - \mu_2)^2 + (\sigma_1^2 - \sigma_2^2) + 2(1 - \rho)\sigma_1\sigma_2$$

Thus a perfect reliability is attained if and only if $\mu_1 = \mu_2$, $\sigma_1 = \sigma_2$, and $\rho = 1$. To obtain a coefficient with values between -1 and 1 , Lin³ defines the *concordant correlation coefficient* as

$$\rho_{con} = 1 - \frac{E[(Y_1 - Y_2)^2]}{\sigma_1^2 + \sigma_2^2 + (\mu_1 - \mu_2)^2}$$

Equivalently, we have $\rho_{con} = \rho C_b$, where $C_b = 2/(v + 1/v + u^2)$, $v = \sigma_1/\sigma_2$, and $u = (\mu_1 - \mu_2)/(\sigma_1\sigma_2)^{1/2}$. The factor C_b takes its values between 0 and 1 , and is said to be a bias correction for ρ (when the issue is evaluating reliability) because $|\rho_{con}| \leq |\rho|$. Concordance correlation can be easily estimated by plugging in sample versions of μ_1 , μ_2 , σ_1^2 , σ_2^2 , and ρ .^[3]

Concordance correlation for assessing reliability is an attractive concept that can be generalized to more than two repeated measurements. However, it does not take into account the “random source” of the d measurements. For example, in interrater reliability, concordance correlation will inform us about the reliability of the d raters in the sample. But the result cannot be generalized to other raters. If the raters in the sample are thought to be randomly selected from a larger population of raters, one has to use the concept of intraclass correlation. This is the topic of the next two sections.

INTRACLAS CORRELATION

Let us consider a sample of repeated measurements Y_{ij} , for $i = 1, \dots, n$ and $j = 1, \dots, d$, as in the section “Different Aspects of Reliability.” We may distinguish two situations. If j indexes a particular criterion, such as time or rater, the ordering of the d measurements $Y_{i1}, \dots, Y_{id}$ made on an entity i is not arbitrary and one cannot exchange them. For example, the j th measurement may refer to the result of the j th trial (for test–retest reliability), or to the rating of the j th rater (for interrater reliability). On the other hand, if the ordering of j within i is arbitrary, it is not meaningful to refer to the j th measurement of an entity because the d measurements are interchangeable.

A historical explanation for $d = 2$ can be found in the work of Fisher,^[4] where a (fictive) example with measurements made on pairs of brothers is considered. The first situation above arises when a pair of brothers can be systematically classified into two categories (or two classes),

such as the younger and the elder brother. If one is interested to calculate the correlation between the younger brother and the elder brother, one may use the standard product–moment correlation coefficient, which in this case may be referred to as *interclass correlation*. But if no such classifying criterion is available, for example if we consider twins, the ordering of the two brothers is arbitrary and this is the second situation above. In this case, one cannot define something like a correlation between “this” brother and “that” brother. One can only refer to “the correlation between two brothers,” and this is an example of what is called *intraclass correlation*.

When analyzing repeated measurements of the first kind, i.e., when one may distinguish among the d measurements, a useful model is given by

$$Y_{ij} = \mu + s_i + r_j + e_{ij} \quad (1)$$

where μ is a fixed parameter, and where s_i , r_j , and e_{ij} are mutually independent random effects which are normally distributed with mean 0 and variances σ_s^2 , σ_r^2 , and σ_e^2 , respectively. Note that model 1 may be overly simplistic in some cases. In particular, it assumes that variances σ_r^2 and σ_e^2 do not depend on the size of measurements. In some cases, the assumptions of the model are better fulfilled for transformed data than for raw data.

Let us first consider the (interclass) correlation between two *specific* measurements j_1 and j_2 . Under model 1, this correlation does not depend on the particular values of j_1 and j_2 and is given by

$$\rho_{ic1} = \frac{\text{Cov}(Y_{ij1}, Y_{ij2})}{\sqrt{\text{Var}(Y_{ij1})\text{Var}(Y_{ij2})}} = \frac{\sigma_s^2}{\sqrt{(\sigma_s^2 + \sigma_e^2)(\sigma_s^2 + \sigma_e^2)}} = \frac{\sigma_s^2}{\sigma_s^2 + \sigma_e^2}$$

Note that the denominator of ρ_{ic1} is equal to the variance of measurements Y_{ij} conditionally on j (and hence does not involve σ_r^2), such that ρ_{ic1} may also be referred to as the correlation between Y_{ij1} and Y_{ij2} conditionally on j_1 and j_2 (with $j_1 \neq j_2$).

If one wishes to define the (intraclass) correlation between two *arbitrary* measurements in this context, one should consider the correlation between Y_{ij1} and Y_{ij2} unconditionally on j_1 and j_2 (with $j_1 \neq j_2$). One will obtain

$$\rho_{ic2} = \frac{\text{Cov}(Y_{ij1}, Y_{ij2})}{\text{Var}(Y_{ij})} = \frac{\sigma_s^2}{\sigma_s^2 + \sigma_r^2 + \sigma_e^2}$$

Here the denominator is equal to the variance of measurements Y_{ij} unconditionally on j such that σ_r^2 is involved and $\rho_{ic2} \leq \rho_{ic1}$.

When the ordering of the d measurements is arbitrary, the term r_j in model 1 does not make sense. Thus, one has to assume a simpler model, for example

$$Y_{ij} = \mu + s_i' + e_{ij}' \quad (2)$$

where μ is a fixed parameter, and where s'_i and e'_{ij} are mutually independent random effects which are normally distributed with mean 0 and variances σ_s^2 and σ_e^2 , respectively. In this context, it is not possible to define the correlation between two specific measurements, while the correlation between two arbitrary measurements is given by

$$\rho_{ic3} = \frac{\text{Cov}(Y_{ij1}, Y_{ij2})}{\text{Var}(Y_{ij})} = \frac{\sigma_s^2}{\sigma_s^2 + \sigma_e^2}$$

At first sight, one may think that models 1 and 2 are equivalent by letting $s'_i = s_i$ and $e'_{ij} = r_j + e_{ij}$. But one would have then $\text{Cov}(e'_{i1j1}, e'_{i2j2}) = \sigma_r^2/d$ for $i_1 \neq i_2$, such that the independency assumptions of model 2 would no longer hold as soon as $\sigma_r^2 > 0$.

All three coefficients ρ_{ic1} , ρ_{ic2} , and ρ_{ic3} are sometimes referred to as intraclass correlation in the literature, but ρ_{ic1} should better be referred to as interclass correlation, as explained above.

ASSESSING INTRATER, INTERRATER, AND TEST-RETEST RELIABILITY

The ordering of repeated measurements for interrater data and test-retest data is clearly not arbitrary and one should use model 1. The term s_i represents the subject effect, whereas r_j is the systematic error (a “rater effect” for interrater data, or a “trial effect” for test-retest data) and e_{ij} is the random error. Thus, the amount of systematic error and random error may be quantified by σ_r^2 and σ_e^2 , respectively. From the definition of coefficients ρ_{ic1} and ρ_{ic2} given in the previous section, we see that ρ_{ic2} takes into account the systematic error, whereas ρ_{ic1} does not.

Coefficient ρ_{ic1} is the “correlation between two specific raters” for interrater data and the “correlation between two specific (for example two successive) trials” for test-retest data. In contrast, ρ_{ic2} should simply be referred to as the “correlation between two raters” or as the “correlation between two trials” (where raters and trials might change from one entity to another). Following Rousson et al.,^[5] we recommend the use of ρ_{ic2} to assess interrater reliability, because a systematic error clearly indicates a failure in reliability and should be penalized. For test-retest data, on the other hand, a systematic error is often attributable to a learning effect (improvement in the retest situation) or to a fatigue effect (worsening in the retest situation), which are not directly related to reliability. Thus, we advocate the use of ρ_{ic1} to assess test-retest reliability.

For intrarater data, it is not always clear whether or not the ordering of repeated measurements is arbitrary. If one suspects a learning effect for the rater, one may consider the ordering in which the ratings were carried out and use model 1. Because such a learning effect should not occur for well-trained raters, and hence indicates a lack of reliability,

one may then use ρ_{ic2} to assess intrarater reliability. On the other hand, if no learning effect is expected, one may use model 2 and ρ_{ic3} . But as the systematic error is, in general, negligible for intrarater data, the choice between models 1 and 2, and coefficients ρ_{ic1} , ρ_{ic2} , and ρ_{ic3} is not crucial.

In some instances, models different from Eq. 1 or Eq. 2 are needed. For interrater data, model 1 implicitly assumes that the d raters are a random sample from a potentially large population of raters. If the d raters are the only raters of interest, one may prefer to consider a fixed rater effect r_j , rather than a random one (such that $r_1, r_2, \dots, r_d$ are the whole population of r_j). In this case, model 1 should be parametrized such that $\sum_j^d = 1$ $r_j = 0$, while the amount of systematic error may be quantified by $\tilde{\sigma}_r^2 = \sum_{j=1}^d r_j^2 / (d-1)$. Then, interrater reliability can be assessed by $\tilde{\rho}_{ic2} = \sigma_s^2 / (\sigma_s^2 + \tilde{\sigma}_r^2 + \sigma_e^2)$. For test-retest data, the distinction between a model with fixed or random r_j is not important because we do not take into account the effect r_j in the definition of reliability.

Finally, one may simultaneously assess several aspects of reliability, such as intrarater and interrater reliability, by using a three-dimensional array of data, where Y_{ijk} denotes the k th rating of the j th rater made on the i th subject (for $i = 1, \dots, n$, $j = 1, \dots, d$ and $k = 1, \dots, m$). In this case, one could consider a model such as

$$Y_{ijk} = \mu + i_i + j_j + k_k + ij_{ij} + ik_{ik} + jk_{jk} + ijk_{ijk} \quad (3)$$

where μ is a fixed parameter, and where i_i , j_j , k_k , ij_{ij} , ik_{ik} , jk_{jk} , and ijk_{ijk} are mutually independent random effects which are normally distributed with mean 0 and variances σ_i^2 , σ_j^2 , σ_k^2 , σ_{ij}^2 , σ_{ik}^2 , σ_{jk}^2 , and σ_{ijk}^2 , respectively. The “total variance” of measurements Y_{ijk} is given by the sum of all these variances. Then, one could assess interrater reliability by the percentage of this total variance which is not attributable to the raters, i.e., by

$$\frac{\sigma_i^2 + \sigma_k^2 + \sigma_{ik}^2}{\sigma_i^2 + \sigma_j^2 + \sigma_k^2 + \sigma_{ij}^2 + \sigma_{ik}^2 + \sigma_{jk}^2 + \sigma_{ijk}^2}$$

Similarly, intrarater reliability can be assessed by

$$\frac{\sigma_i^2 + \sigma_j^2 + \sigma_{ij}^2}{\sigma_i^2 + \sigma_j^2 + \sigma_k^2 + \sigma_{ij}^2 + \sigma_{ik}^2 + \sigma_{jk}^2 + \sigma_{ijk}^2}$$

whereas a “global” coefficient of reliability can be obtained as

$$\frac{\sigma_i^2}{\sigma_i^2 + \sigma_j^2 + \sigma_k^2 + \sigma_{ij}^2 + \sigma_{ik}^2 + \sigma_{jk}^2 + \sigma_{ijk}^2}$$

All these reliability coefficients are defined as ratios of variances and assume values between 0 and 1. Thus, they have the particularity to be always positive (unlike their estimates introduced in the section “Estimation,” which may happen to be negative) and may be interpreted

as “percentage of variance explained” (without being squared). In general, they represent the percentage of variance in the measurements that is due to the subject effect, i.e., which is not attributable to measurement error, such that the higher this percentage, the better the reliability. Simplicity of interpretation makes these coefficients particularly attractive to assess reliability, compared to other approaches.

ESTIMATION

While sample correlation will generally underestimate ρ_{ic2} and ρ_{ic3} (as already mentioned in the section “Concordance Correlation”), it is a valid estimate of ρ_{ic1} (in the case $d = 2$). On the other hand, sample correlation calculated from all $nd(d-1)$ pairs of observation (X_{ij1}, X_{ij2}) (with $i = 1, \dots, n, j_1, j_2 = 1, \dots, d$ and $j_1 \neq j_2$), where each observation X_{ij} appears $2(d-1)$ times, is a valid estimate of ρ_{ic3} . More efficient estimates using the assumptions of the model are obtained by performing an analysis of variance for repeated measurements.^[6] From data Y_{ij} , we calculate the following sums of squares

$$\begin{aligned} SS_s &= d \sum_{i=1}^n (\bar{Y}_i - \bar{Y}_{..})^2 \\ SS_r &= n \sum_{j=1}^d (\bar{Y}_j - \bar{Y}_{..})^2 \\ SS_e &= \sum_{i=1}^n \sum_{j=1}^d (Y_{ij} - \bar{Y}_i - \bar{Y}_j + \bar{Y}_{..})^2 \end{aligned}$$

where $\bar{Y}_i = \sum_{j=1}^d Y_{ij} / d$, $\bar{Y}_j = \sum_{i=1}^n Y_{ij} / n$ and $\bar{Y}_{..} = \sum_{i=1}^n \sum_{j=1}^d Y_{ij} / (nd)$. Under model 1, quantities $MS_s = SS_s / (n-1)$, $MS_r = SS_r / (d-1)$, and $MS_e = SS_e / (n-1)(d-1)$ have expectations $d\sigma_s^2 + \sigma_e^2$, $n\sigma_r^2$ and σ_e^2 , respectively. Thus, unbiased estimates of σ_s^2 , σ_r^2 and σ_e^2 are obtained as

$$\begin{aligned} \hat{\sigma}_s^2 &= \frac{MS_s - MS_e}{d} \\ \hat{\sigma}_r^2 &= \frac{MS_r - MS_e}{n} \\ \hat{\sigma}_e^2 &= MS_e \end{aligned}$$

Then, an estimate of ρ_{ic1} is given by

$$R_{ic1} = \frac{\hat{\sigma}_s^2}{\hat{\sigma}_s^2 + \hat{\sigma}_e^2} = \frac{MS_s - MS_e}{MS_s + (d-1)MS_e}$$

while an estimate of ρ_{ic2} is given by

$$R_{ic2} = \frac{\hat{\sigma}_s^2}{\hat{\sigma}_s^2 + \hat{\sigma}_r^2 + \hat{\sigma}_e^2} = \frac{MS_s - MS_e}{MS_s + (d-1)MS_e + (d/n)(MS_r - MS_e)}$$

Under model 1 with fixed effect r_j , R_{ic2} is also an estimate of $\tilde{\rho}_{ic2}$.

For model 2, R_{ic1} and R_{ic2} are similar and both are valid estimates of ρ_{ic3} . A more efficient estimate of ρ_{ic3} was proposed in 1899 by Pearson et al.^[7] and is given by

$$R_{ic3} = \frac{MS_s - MS_w}{MS_s + (d-1)MS_w}$$

where $MS_w = SS_w / (n(d-1))$ and

$$SS_w = \sum_{i=1}^n \sum_{j=1}^d (Y_{ij} - \bar{Y}_i)^2 = SS_r + SS_e$$

Contrary to R_{ic1} and R_{ic2} , estimate R_{ic3} provides exactly the same value when the ordering of repeated measurements is altered for some entities.

Coefficient R_{ic3} is the most widely used estimate of intraclass correlation in the literature. Note, however, that $MS_w = \hat{\sigma}_r^2 + \hat{\sigma}_e^2$ and $(MS_s - MS_w)/d = \hat{\sigma}_s^2 - \hat{\sigma}_r^2/d$. Thus, under model 1, R_{ic3} is an estimate of

$$\frac{\sigma_s^2 - \sigma_r^2/d}{\sigma_s^2 + \sigma_r^2 + \sigma_e^2 - \sigma_r^2/d}$$

and will underestimate both ρ_{ic1} and ρ_{ic2} . If an ordering of repeated measurements can be defined, it is important to sort the data (such that the j th measurement has the same meaning for each entity) and to use R_{ic1} (if one does not wish to penalize σ_r^2) or R_{ic2} (if one wishes to penalize σ_r^2) rather than R_{ic3} , otherwise one will underestimate intraclass correlation.

If one wishes to estimate coefficients for more complicated models, such as model 3, one will face a problem of variance components estimation. For a good overview of the topic, see, e.g., Searle et al.^[8] There the problem of estimation for “unbalanced data” is also considered, for which the method of restricted maximum likelihood can be used.

To approximately satisfy the normality and homoscedasticity assumptions, reliability data of Fig. 1 were log-transformed. Coefficients R_{ic1} , R_{ic2} , and R_{ic3} calculated on such transformed data are given in Table 1. Following the arguments given in the previous section, reliability is estimated to be 0.98 for intrarater data, 0.96 for interrater data and 0.81 for test–retest data.

Table 1 Estimates of Intraclass Correlation for the Data of Fig. 1 (log-Transformed)

Panel	Type of reliability	R_{ic1}	R_{ic2}	R_{ic3}
(a)	Interrater data	0.97	0.96	0.96
(b)	Interrater data	0.98	0.96	0.96
(c)	Intrarater data	0.98	0.98	0.98
(d)	Test–retest data	0.81	0.74	0.73

CONFIDENCE INTERVALS

It is not meaningful to test for a “statistically significant” reliability (because this would just prove that the reliability is larger than 0, which is trivial). To assess how well reliability is estimated, a confidence interval is needed. In practice, the minimum acceptable value for a reliability coefficient is often set to 0.75 or 0.80.^[9] Thus a necessary condition to prove that reliability is acceptable is to obtain at least 0.75 as lower boundary of a 95% confidence interval.^[10]

Exact confidence intervals for ρ_{ic1} and ρ_{ic3} can be derived. Under model 1, $SS_s/(d\sigma_s^2 + \sigma_e^2)$ follows a chi-square distribution with $n-1$ degrees of freedom, while SS_e/σ_e^2 follows a chi-square distribution with $(n-1)(d-1)$ degrees of freedom. Moreover, these two quantities are independent. As a consequence, a confidence interval for ρ_{ic1} at the level $1-\alpha$ may be obtained from

$$1-\alpha = \Pr \left\{ \frac{\frac{MS_s}{MS_e} - F_{1-\alpha/2}}{\frac{MS_s}{MS_e} + (d-1)F_{1-\alpha/2}} \leq \rho_{ic1} \leq \frac{\frac{MS_s}{MS_e} - F_{\alpha/2}}{\frac{MS_s}{MS_e} + (d-1)F_{\alpha/2}} \right\}$$

where F_α denotes the α -quantile of an F -distribution with $n-1$ and $(n-1)(d-1)$ degrees of freedom. Similarly, under model 2, a confidence interval for ρ_{ic3} at the level $1-\alpha$ may be obtained from

$$1-\alpha = \Pr \left\{ \frac{\frac{MS_s}{MS_w} - F_{1-\alpha/2}^*}{\frac{MS_s}{MS_w} + (d-1)F_{1-\alpha/2}^*} \leq \rho_{ic3} \leq \frac{\frac{MS_s}{MS_w} - F_{\alpha/2}^*}{\frac{MS_s}{MS_w} + (d-1)F_{\alpha/2}^*} \right\}$$

where F_α^* denotes the α -quantile of an F -distribution with $n-1$ and $n(d-1)$ degrees of freedom.

Confidence intervals for ρ_{ic2} are much more problematic. The approximate confidence interval for ρ_{ic2} proposed by Fleiss and Shrout¹¹ is often used in practice. But while asymptotically exact when both n and d tend to infinity, this method produces confidence intervals that are too liberal when d is small, and this becomes even worse when n increases. The proposal of Zou and McDermott¹² does not solve this problem and often produces confidence intervals that are not informative, i.e., which have a very low lower bound (close to 0, or even a negative value), and this holds also when the true value of ρ_{ic2} is high and n is large. This phenomenon persists when using an asymptotically exact solution for fixed d and n tending to infinity,^[13,14] and is unavoidable when d is small and the ratio σ_r^2/σ_e^2 is

not negligible.^[15] For interrater reliability, this means that even when the true reliability ρ_{ic2} is large, one will not be able to prove it from a sample with few raters if the ratio “systematic error to random error” is not negligible.

To obtain informative and conservative confidence intervals for interrater reliability, Rousson et al.¹⁵ proposed an approach related to a sensitivity analysis. This approach assumes that the raters are well-trained such that σ_r^2/σ_e^2 is not too large, for example not larger than 1. In that paper, an informative and conservative confidence interval for coefficient $\tilde{\rho}_{ic2}$ is also provided, which uses quantiles of a noncentral F -distribution.

HOW TO IMPROVE RELIABILITY

A low intrarater or interrater reliability may indicate that the raters are not well trained or that the variable to be measured is not well defined or standardized. Thus, a first step to improve reliability is a better training of the raters and the introduction of better standards of measurement. In particular, the rater effect r_j in model 1 should become negligible for well-trained raters. Test-retest reliability is related to fluctuations in the state of a subject and is hence more difficult to improve.

If reliability remains low despite a good standardization, one may use an average of m measurements instead of a single measurement. This will reduce the amount of random error by a factor m . For example, blood pressure is often routinely assessed by an average of two measurements made some minutes apart. For interrater reliability, the use of an average of m ratings made by m different raters will also reduce the amount of systematic error by a factor m . From a sample of d repeated measurements, reliability of an average of m measurements can thus be estimated by

$$R_{ic1,m} = \frac{MS_s - MS_e}{MS_s + (d-m)MS_e/m}$$

$$R_{ic2,m} = \frac{MS_s - MS_e}{MS_s + (d-m)MS_e/m + (d/n)(MS_r - MS_e)/m}$$

$$R_{ic3,m} = \frac{MS_s - MS_w}{MS_s + (d-m)MS_w/m}$$

for test-retest, interrater, and intrarater reliability, respectively. Note that when $m = d$, the first coefficient above is equal to the well-known Cronbach's alpha^[16] for assessing the internal consistency of the d measurements.

In social sciences, it is common to use “component of variables” rather than single variables to obtain fewer and better interpretable information. As a by-product, reliability is also improved. For simplicity, let us consider m variables that are equally reliable and equally correlated with each other. Let us consider the case of zero systematic error, such that the reliability of a single variable is given

by $\sigma_s^2/(\sigma_s^2 + \sigma_e^2)$, and let $\rho \geq 0$ be the correlation between two of these variables. Then, the reliability of the average (or the sum) S_m of the m variables is given by

$$\frac{\sigma_s^2}{\sigma_s^2 + \frac{\sigma_e^2}{1 + \rho(m-1)}}$$

Thus, reliability of component S_m will be higher than reliability of a single variable whenever $\rho > 0$ and $m > 1$. Moreover, reliability of S_m is an increasing function of ρ and m . In particular, it tends to 1 when m tends to infinity (if $\rho > 0$). For neuromotor data, for example, test–retest reliability of an average of 12 different timed performances (appropriately standardized) is higher than test–retest reliability of a single timed performance.^[5]

MEASURING AGREEMENT

As stated in the “Introduction” section, reliability and agreement are related but nevertheless two different concepts. Bland and Altman^[17] point out the drawbacks of intraclass correlation for evaluating the agreement between two measuring instruments. They note that it depends on the range of measurements, such that a low value of

intraclass correlation may just be the consequence of a low variability between the entities in the sample. Moreover, it is not related to the size of measurement error, which might be clinically tolerable.

To assess the agreement between two measuring instruments (such as a new technique and an established one to see whether the former is accurate enough to replace the latter), Bland and Altman^[17,18] propose to calculate differences $D_i = Y_{i2} - Y_{i1}$ of measurements provided by the two instruments (on $i = 1, \dots, n$ entities). When D_i is approximately normally distributed, about 95% of them will lie in the interval $[\bar{D} - 2S_D, \bar{D} + 2S_D]$, which they call *limits of agreement*, where $\bar{D} = \sum_{i=1}^n D_i/n$ and $S_D^2 = \sum_{i=1}^n (D_i - \bar{D})^2/(n-1)$. This method does not depend on the range of measurements, and limits of agreement indicate whether discrepancies are acceptable in practice based on clinical arguments. Moreover, a plot of these differences D_i vs. average measurements $M_i = (Y_{i1} + Y_{i2})/2$ allows the detection of possible trends in systematic error and/or in random error. If some transformation of the data is needed to satisfy the normality assumption, however, limits of agreement are no longer directly related to the scale of the data and are more difficult to interpret.

Let us see how limits of agreement are related to the concepts introduced in the section “Intraclass Correlation.” Under model 1, quantities $\bar{D}$ and S_D^2 are estimates of $r_2 - r_1$

Fig. 2 Limits of agreement for the timed performance (in seconds) of some neuromotor task: (a and b) interrater data, (c) intrarater data, (d) test–retest data. Estimate of interval I_2 was used for (a)–(c), and of interval I_1 for (d). A line indicating the center of the intervals is also plotted. The x-axis refers to the average of two measurements and the y-axis to the differences between two measurements

and $2\sigma_e^2$, respectively (we actually have $S_D^2 = 2\hat{\sigma}_e^2$). Therefore limits of agreement of Bland and Altman estimate the interval

$$I_1 = [r_2 - r_1 - 2\sqrt{2\sigma_e^2}; r_2 - r_1 + 2\sqrt{2\sigma_e^2}]$$

which refers to differences between two specific measurements. On the other hand, if one wishes limits of agreement for differences between two arbitrary measurements, one should consider the interval

$$I_2 = [-2\sqrt{2(\sigma_r^2 + \sigma_e^2)}; 2\sqrt{2(\sigma_r^2 + \sigma_e^2)}]$$

which can be estimated by plugging in estimates $\hat{\sigma}_r^2$ and $\hat{\sigma}_e^2$ introduced in the section “Estimation.” Contrary to I_1 , interval I_2 is centered at 0 and is also defined for $d > 2$ repeated measurements.^[5]

Following the arguments in the section “Assessing Intrarater, Interrater, and Test–Retest Reliability,” limits of agreement I_1 could be used to assess the accuracy of measurements in a test–retest situation, while I_2 could be used for assessing accuracy of interrater or intrarater data. Fig. 2 shows limits of agreement for the data plotted in Fig. 1. The estimate of I_2 is $[-1.2, 1.2]$ for intrarater data and $[-2.0, 2.0]$ for interrater data. Thus, 95% of the times, two ratings of a same rater will not differ more than 1.2 sec. On the other hand, two ratings of two different raters (randomly selected from a larger population of raters) will not differ more than 2 sec. For test–retest data, the estimate of I_1 is $[-5.3, 2.6]$ and hence the second trial can be up to 5.3 sec faster than the first one. From the plot of test–retest data, one may also see some possible negative trend in systematic error (meaning that the learning effect is more important for those children with a bad performance) and some positive trend in random error.

While useful for assessing the accuracy of measurements for a normally distributed variable, limits of agreement are inappropriate for assessing reliability, as soon as several variables with different scales are involved. For example, one cannot compare the reliability of different tools for assessing neuromotor development, or of different psychological tests, using limits of agreement. For this, intraclass correlation is the method of choice because it does not depend on the scale of the data.

CONCLUSION

Reliability can be appropriately assessed using intraclass correlation. This informs us about the percentage of variability in measurements which is not a result of measurement error, and is hence easily interpretable and useful for comparing the reliability of different variables. As intraclass correlation depends on the range of measurements, it is important to use a sample which is representative of the

population of interest. Different definitions and estimates of intraclass correlation should be used depending on the situation. In this entry, we have focused on three estimates denoted by R_{ic1} , R_{ic2} , and R_{ic3} . We have argued that one should use the first one if there is a systematic error which is not related to reliability (as for test–retest data), the second one if there is a systematic error which is related to reliability (as for interrater data), and the third one if no systematic error is expected (as it may happen for intrarater data).

Abstract

This entry reviews and summarizes various strategies for dealing with missing data problems in repeated measurement designs that have been suggested to date.

INTRODUCTION

Repeated measurement designs are popular in clinical trials for studies comparing the efficacy of several non-curative treatments because they can effectively remove within-subject variances, by taking repeated measurements from each subject with different treatments. However, by the very nature of taking repeated measurements, they also suffer from the common problem of missing values on one or more occasions. Complete data sets are typically unavailable for various reasons.

In repeated measurement designs, the missing data problem can be viewed as a general problem of missing observations in multivariate data. Analysis issues related to the bivariate or multivariate normal distribution with missing observations has been quite extensively discussed in the literature.

In this entry, we review and summarize various strategies for dealing with missing data problems in repeated measurement designs that have been suggested to date. Our discussion is limited to data with an approximately multivariate normal distribution where the missing data occur on the outcome variable. We first discuss various forms of missing data mechanisms and analytic strategies for dealing with missing data problems. Then, we focus on strategies for use with incomplete repeated measures data in small samples. We also review another approach that utilizes proxy information in lieu of dealing with missing values in the traditional manner.

MISSING DATA MECHANISM

When taking repeated observations,^[1–4] there are various reasons for having missing values. In most studies, unobserved data are treated as “missing,” in the sense that there are true underlying values that could have been observed but were not. However, depending on how the data have become missing, treating unobserved data simply as missing can lead to a serious estimation bias.^[5–7] This section reviews several possible types of missing data, limiting to the case where the missing data occur on the outcome variable.

The most appropriate way to handle missing or incomplete data depends on how the data points became missing. Little and Rubin^[8] define three unique types of missing data mechanisms, distinguishing among the different situations according to how the data became missing and incomplete. They are divided into three different situations. The data can be missing completely at random (MCAR), missing at random (MAR), or there can be nonignorable missing data (NMD).

The MCAR situation assumes that the reasons why the data are missing are completely unrelated to the data (both response and covariates). That is, cases with complete data are indistinguishable from cases with incomplete data. Observed units are random samples of the sampled units. Heitjan^[9] provides an example of MCAR data where a research associate shuffles raw data sheets and arbitrarily discards some of the sheets. The discarded

sheets have no particular reason to be discarded and completely random and independent of what could have been observed and the associated covariates. Graham et al.^[10] illustrate the use of planned missing data patterns of this type. In such situations, data analyses based on complete subset data are unbiased, although it may lose statistical power.

The MAR situation occurs when the observed units are not necessarily a random subsample of the sampled units, but they are a random sample of the sampled values within subclasses defined by values of covariates. For example, if participants with low self-esteem in a study are less likely to return for follow-up sessions, then the observed data are not a random subsample in the study, but they are a random sample of the sampled values within subclasses defined by the values of self-esteem. In these two MCAR and MAR situations, the missing-data mechanisms are ignorable for likelihood-based inferences.^[8]

In NMD situation, the probability that the data are observed depends on the value of the outcome and varies across the levels of the covariates. In the above example of MAR situation, if the observed data are not a random subsample even among the subclasses defined by self-esteem or any other covariates, we have the NMD situation. Therefore the missing data are nonignorable, and analyses on the reduced sample that does not allow for the missing data mechanism are subject to bias.

In practice, it is often difficult to make the MCAR assumption, because there is often some degree of relationship between missing values and other observed data. Therefore the pattern of MAR is an assumption that is most often, but not always, tenable.

GENERAL APPROACHES TO MISSING DATA

Analysis techniques that deal with incomplete or missing data are useful and necessary, especially for experiments involving human subjects, because in these cases, the data are usually expensive, scarce, or significant. For any missing data methods to be effective, they should incorporate a specific missing data mechanism into their development. For missing data problems, three general approaches have been used, most of which were built based on the MAR assumption.

The first is the traditional approach of using only complete data subsets. However, this approach has been widely criticized, because it produces inconsistent estimators when missing data are not missing at random.^[11] This shortcoming has led many investigators to develop a second approach: efficient incomplete data analysis methods, using all available data (e.g., Refs. [5,6,12–14]). A third approach considers imputing missing data.^[15] An advantage of this latter approach is that one can use standard statistical software to analyze the resulting completely filled data.

Some missing data approaches tend to be computer intensive. Bayesian and/or simulation approaches have also been used. With the advancement of computer technology in recent years, more computer-intensive techniques such as the Gibbs sampler have gained popularity. See Ref. [16] for reviews on these various missing data-analysis methods.

The distribution theory for most of the resulting estimators has been based on an asymptotic normal distribution theory assuming large samples. The testing procedures involving missing data with small samples need to be developed further, even for bivariate sets of data. It has been shown that using almost maximum likelihood estimators is generally most powerful when the number of complete pairs of observations is moderately large (larger than 20) and the correlation is in the range of 0.3–0.9.^[17,18]

INCOMPLETE REPEATED MEASURES DATA ANALYSES

Investigators of repeated measurement designs (RMD) typically deal with small sample data. For this reason, an analysis method that does not rely too heavily on computational aspects may be desirable and feasible where the approximate distributions can be obtained. This entry reviews such methods for small sample repeated measures data analyses with missing values.

We denote a repeated measurement design with t treatments, p periods, and s sequences (groups) as RMD (t, p, s). For example, the simple two-period, two-treatment (A and B) crossover design, where subjects are assigned to the treatment sequences AB and BA, occurs frequently in practice. Data are obtained over two periods on two treatments, with two observations per subject. Each subject receives one treatment during the first period, and the other treatment during the second period. This idea has a strong appeal among physicians and pharmaceutical researchers especially. See Refs.[1–4] for general design issues with repeated measures data.

Generally, crossover designs have been the design of choice, when recruiting study subjects is expensive or the response is expected to show high variability among study subjects. However, if some subjects have missing data in one or more occasions in a general RMD (t, p, s), we are concerned with how to best and effectively deal with the situation.

Consider the model popularly employed:

$$y_{ijk} = \mu + \pi_i + \tau_t + \gamma_t + \lambda_k + \varepsilon_{ijk} \quad (3.1)$$

where y_{ijk} is the response from subject j in period i and sequence k , for $i = 1, \dots, p$, $j = 1, \dots, n_k$, and $k = 1, \dots, s$, μ is the overall mean, π_i is the effect of period i , τ_t is the effect of treatment t , γ_t is the residual effect of treatment t , λ_k is the effect of sequence k , and ε_{ijk} is the measurement error. Another popular form of model 3.1 can include random

subject effects instead of the fixed sequence effects λ_k to accommodate dependencies among the repeated measures data.^[2-5]

Rewrite model 3.1 in matrix form as

$$\mathbf{y} = \mathbf{Z}\mathbf{X}\boldsymbol{\beta} + \mathbf{e} = \mathbf{Z}\boldsymbol{\mu} + \mathbf{e}$$

where $\mathbf{y}$ is the vector of responses, $\mathbf{Z}$ is an incidence matrix of ones and zeros, which equals to an identity matrix when there are no missing values, and $\mathbf{X}$ is a design matrix that relates the cell mean parameters to the repeated measurement design model parameters $\boldsymbol{\beta}$. The $\mathbf{e}$ is a vector of errors that has a mean zero with $\text{Cov}(\mathbf{e}) = \mathbf{V}$. When the variance-covariance matrix $\mathbf{V}$ is known, the maximum likelihood estimator for $\boldsymbol{\beta}$ is obtained as $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{W}^{-1}\mathbf{X})^{-1}(\mathbf{X}'\mathbf{W}^{-1}\hat{\boldsymbol{\mu}})$ with $\text{Cov}(\hat{\boldsymbol{\beta}}) = (\mathbf{X}'\mathbf{W}^{-1}\mathbf{X})^{-1}$ where $\mathbf{W} = (\mathbf{Z}'\mathbf{V}^{-1}\mathbf{Z})^{-1}$ and $\hat{\boldsymbol{\mu}} = (\mathbf{Z}'\mathbf{V}^{-1}\mathbf{Z})^{-1}(\mathbf{Z}'\mathbf{V}^{-1}\mathbf{y})$. For $\mathbf{V}$ unknown, Carrière^[5,6] used $\hat{\mathbf{V}}$ for $\mathbf{V}$. Then, the estimated treatment effect τ_t and its variance are $\tau_t = \mathbf{c}'_{1t}\boldsymbol{\beta}$ and $\text{var}(\hat{\tau}_t) = \mathbf{c}'_{1t}(\mathbf{X}'\hat{\mathbf{W}}^{-1}\mathbf{X})^{-1}\mathbf{c}_{1t}$ and those for residual effect γ_t are $\hat{\gamma}_t = \mathbf{c}'_{2t}\boldsymbol{\beta}$ and $\text{var}(\hat{\gamma}_t) = \mathbf{c}'_{2t}(\mathbf{X}'\hat{\mathbf{W}}^{-1}\mathbf{X})^{-1}\mathbf{c}_{2t}$ for treatment and residual effect vectors $\mathbf{c}_{1t}$ and $\mathbf{c}_{2t}$ for treatment t . Carrière^[5,6] gave detailed estimation results for specific designs.

Consider a two-treatment design, where missing data occur at random. The hypotheses we are interested in testing are that there are no direct treatment effect contrast

$$H_{01} : \tau = 0$$

for $\tau = (\tau_1 + \tau_2)/2$, and no residual treatment effect contrast

$$H_{02} : \gamma = 0$$

for $\gamma = (\gamma_1 + \gamma_2)/2$. The test statistics investigators consider are of the form

$$t_\gamma = \frac{\hat{\gamma}}{\sqrt{\text{var}(\hat{\gamma})}}, \text{ and } t_\tau = \frac{\hat{\tau}}{\sqrt{\text{var}(\hat{\tau})}} \quad (3.2)$$

where var is the estimated variance for estimator $\hat{\tau}$ or $\hat{\gamma}$, obtained as above.^[5,6]

The distribution of the statistics in Eq. 3.2 is then approximated suitably.^[5,6] Specifically, assuming that missing values occur in a nested pattern, which is quite plausible in general longitudinal data, a small sample testing procedure with missing data has been developed.^[5-7,18] Such an approach makes maximal use of all available information and is more powerful than an analysis that considers complete subset data only.

The derivation of an approximate distribution of the statistics in Eq. 3.2 first recognized that the analysis based on complete subset data uses the exact t distributions for the statistics in Eq. 3.2 with degrees of freedom of $N^{(L)} - s$ and $(p - 1)(N^{(L)} - s)$, respectively, for the model under a general covariance assumption and that under a compound symmetry model.

With incomplete data, Carrière^[5,6] and Patel^[7,18] discussed the rationale for deciding the approximate degrees of freedom for testing H_{01} and H_{02} . For compound symmetry covariance structures, the degrees of freedom are based on those used in the estimated variance component. For the case where the missing data occur in two stages ($L = 2$), $(p - 1)(N^{(L)} - s)$ was suggested for testing both τ and γ , where $N^{(L)}$ is the total number of subjects who completed the trial. When no pattern can be specified for the covariance matrix, the degrees of freedom were proposed once again based on the estimated variances and covariances involved in estimating the variances for τ and γ . They were proposed as $N^{(L)} - s$ for τ , but with the average degrees of freedom for γ , which is $(N^{(L)} + N - 2s - p_1 p_2)/2$, where p_1 is the number of periods with complete set of data up through the first p_1 periods and p_2 is the number of remaining periods with missing data. Their strategies were demonstrated to work well in repeated measurement data in small samples. See Refs. [5,6] for details.

A simulation study of the relative powers and levels of significance for small samples was conducted based on 1000 samples, and the procedure was demonstrated to be valid and preferable to the practice of discarding the incomplete sets. The following is the result of applying the procedure of Carrière^[5,6] to some useful and popular RMDs.

The incomplete data procedure was found to be most helpful for RMD (2, 2, 2) in testing no residual effects, because it increases the power of testing for no residual treatment effects. If one follows the two-step analysis strategy suggested by Grizzle,^[19] it is important to make an effort to increase the power of deciding accurately that there are no residual effects. Hence the incomplete data procedure is strongly recommended for RMD (2, 2, 2).

RMD (2, 3, 2) benefits greatly from the incomplete data procedure. The power increases rather significantly in multiperiod designs, and even more so when the missing data methods are incorporated. The power increases with the increasing level of ρ for testing both no treatment and no residual effects.

For this multiperiod design with $p = 3$, the missing data problem can be considered from another perspective that the design is a result of a planned two-period experiment, with observations of one additional period on a fraction of the subjects. It was shown that even with a dropout rate as high as 80% (or observations available on one additional period from 20% of the subjects), a significant improvement in efficiency can be achieved over two-period designs. Carrière^[2] reports that when one cannot observe a fraction of subjects for one more period, it seems clear that the resulting RMD (2, 2, 2) is of questionable value.

Carrière^[6] also discussed the conventional assumption that any approach would be reasonable with small sample data, because various covariance patterns are indistinguishable because of the sample size being too small. However, she demonstrated that, even for small sample

data, recognizing the correct covariance structure of the data is extremely important in terms of both empirical size and power of testing hypotheses of parameters of interest. The incomplete data procedure is not robust against the assumption about the covariance structure.

Generally, an incomplete data procedure that uses no specific covariance assumptions was clearly robust in comparison with procedures based on the compound symmetry assumption. Furthermore, an incomplete data procedure that assumes a special covariance structure did not maintain the empirical size at the nominal level for data when the assumptions were violated. The impact was greater when the correlation is high and the sample size is large.^[6]

USE OF PROXY INFORMATION

In this section, we consider incorporating proxy information by replacing missing values on some study subjects with approximate information about their possible responses. Huang^[20] considered a strategy for dealing with incomplete data by using proxy information, when such information is available in an attempt to avoid dealing with missing data situations. For example, in cancer clinical trials, some patients may be too sick to respond, but their caregivers are usually on hand to provide pertinent information instead. As another example, unavailable information about a subject's socioeconomic status can be filled in with proxy data about neighborhood affluence. As these two examples illustrate, such information is available in diverse forms and varies a great deal in quality.

The issue then is how to treat proxy information to maximize its usefulness. In principle, this strategy combines all of the three approaches mentioned earlier. It uses a complete data analysis method, fills in for missing values with proxy information, and utilizes all available data. However, this approach differs from the traditional imputation methods in that ours are based on better information than is provided by such impersonal methods as mean imputation or regression imputation using computer software.

Many investigators have shown empirically that there is a high degree of agreement among the responses of study subjects and their proxies, i.e., their care providers.^[21,22] However, we must account for possible systematic bias and heterogeneity of proxy data from the actual responses in statistical analyses of the data. The biggest advantage of incorporating proxy information may be that it avoids the missing data problem so that standard statistical analysis methods can be applied. See Refs. [23–28] for various situations, where the use of proxy was discussed in terms of some statistical criteria.

Assuming that the missing data occur at random, Huang^[20] presented the merits of using proxy data in place of missing values in a multivariate repeated measures data setting. A multiple linear model was considered that

accommodates another set of model parameters and also a different form of covariance matrix due to the use of proxies such that:

$$y_{ijk} = \mu + \pi_i + \tau_j + \gamma_i + \lambda_k + \varepsilon_{ijk} \quad (4.1)$$

$$p_{ijk} = \mu^a + \pi_i^a + \tau_j^a + \gamma_i^a + \lambda_k^a + \varepsilon_{1ijk} + \varepsilon_{2ijk} \quad (4.2)$$

where all terms in Eq. 4.1 are the same as in Eq. 3.1 from the actual observed data except that ε_{ijk} denotes the measurement error. Eq. 4.2 is to model the proxy data, where p_{ijk} is the missing data filled in with its proxy data for subject j who failed to give an actual response y_{ijk} in period i and sequence k , other model parameters with the superscript “a” are the same as in model 3.1, which are to model possible bias of using the proxy data in place of actual responses, and ε_{1ijk} and ε_{2ijk} are the measurement error terms from the actual data and proxy data, respectively. In particular, the proxy data have no bias if all terms in Eq. 4.2 with the superscript “a” are the same as those in Eq. 4.1. Further, the proxy data have the same variability as the actual data, if $\varepsilon_{2ijk} = 0$ for all i, j, k .

Utilizing proxy information and under the assumption of normality, the statistics for testing for the direct treatment and residual treatment effects similar to Eq. 3.2 are also shown to have approximate t -distributions with certain degrees of freedom,^[20] using much the same argument as Carrière^[5,6] and Patel,^[7,18] which was outlined in the previous section. The approximate degrees of freedom depend on the estimated variance and covariances used to build the t -ratios in Eq. 3.2 with proxy data. See also Refs. [5–7,18]. We summarize the findings for the case of monotone missing data in two stages with $p_2 = 1$ (i.e., only the last period has data missing).

If the actual data and the proxy data share a common covariance matrix, the degrees of freedom were set at $d_1 = (p - 1)(N - 2s)$ under the compound symmetry covariance assumption, because it is the degrees of freedom associated with the sum of squared error used. When the covariance matrix is common, but no pattern can be specified, the degrees of freedom were set at $d_2 = N - (3s + p_1)/2$, where d_2 is the average of the degrees of freedom associated with the two associated submatrices of the estimated covariance matrix.^[20]

When the actual data and proxy data do not share a common covariance matrix but are compound symmetry, the same degrees of freedom as above were used, namely $(p - 1)(N^{(L)} - s)$, as in the incomplete data method^[6] because in this case, it was found that proxy information did not affect the estimation of the mean and the variances of τ .^[20] When the different covariance matrix forms are unspecified, the average of the degrees of freedom associated with the three submatrices of the estimated covariance matrix was used and set at $d_3 = (2N - 3s - 2p_1)/3$.^[20] These approximations were demonstrated to work well in the simulation study. In particular, this approach was compared to the

incomplete analytical method summarized in the previous section.^[5,6]

To summarize the impact of using proxy information in lieu of missing values in RMD for selected designs, we consider RMD (2,2,2) and RMD (2,3,2) in small samples of size five subjects in each sequence. As anticipated, the results are highly dependent mainly on whether we can assume that the proxy and actual observed data share a common covariance matrix.^[20]

For RMD (2, 2, 2), when the proxy and actual data share a common covariance matrix, the testing procedure for the residual treatment effect using proxies provided results similar to those for the traditional incomplete data analysis, although the use of proxies appeared to be less efficient. However, the use of proxies appears to be significantly more powerful in testing the direct treatment effects. When the proxy data and actual data do not share a common covariance matrix, there was very little difference between the two approaches. Overall, they performed similarly in this case, although the incomplete method was slightly more powerful for testing. However, use of proxy does not help to alleviate the estimation problem of the traditional design under the unequal residual effect model, because use of proxy information to fill in the missing second period data does not result in any gain or loss in efficiency.

In RMD (2, 3, 2), however, there were substantial differences between the two approaches. When they share a common covariance matrix, for testing τ , the procedure that uses proxies was both more powerful and more prominent than in the RMD (2, 2, 2). For testing γ , the procedure using proxies was also better. In general, the method using proxies appears to be more powerful than is the traditional incomplete data-analysis strategy, especially when the sample size is small. However, the two approaches performed similarly in large samples. When they do not share a common covariance matrix, the incomplete analysis method was substantially more powerful for testing both τ and γ . Huang^[20] considered the impact of proxy data on design issues. For example, it was indicated that even with about 50% of the data filled in with proxies in the third period, the RMD (2, 3, 2) can attain 80% efficiency, as compared to the ideal situation of complete data with actual observations. In general, she discussed that one could design the experiment so that 80% efficiency can be attained, possible because of available proxies.

Therefore it appears that using proxy data to replace missing values is an excellent alternative to conventional strategies for addressing missing data problems. However, this is true only if the proxy data are similar in variability as the actual observed data. Also, the benefit occurs mainly in small samples. Nonetheless, the results are substantial and significant in that, even when over 50% of the data were replaced by proxy information, the efficiency, as compared to the ideal situation of complete actual data, could be over 90%.^[20] Analysts can use the proxy method

while enjoying all the conveniences of standard analysis methods.

CONCLUSION

In this entry, we have discussed the general approaches for dealing with missing data situations when using repeated measurement designs on small samples. Various investigators have shown that using complete subset data while discarding incomplete pairs is inefficient and proposed alternate methodologies. However, to be effective, any missing data procedure must properly recognize the reasons for having missing values. Also, any testing procedure should be suitable for use in practice as well as theory. The methods we reviewed in this entry are not based on iterative techniques or simulated imputations. As with any approximate procedures, appropriate adjustment to the distribution of the test statistics is important.

We focused on incomplete analytical methods for small sample repeated measures data, because most investigators of clinical trials work with such small samples. We applied the incomplete data procedure to selected RMDs and found them to be most helpful for testing for no residual treatment effects in the traditional two-period, two-treatment, two-sequence design because they increase the power of the test. The effect was even more significant in three-period designs. The power increases significantly in multiperiod designs, and even more so when the missing data methods are incorporated.

We also assessed the role of proxy information with a main goal to establish whether collecting proxy information in an effort to optimize the data collection process is useful in missing data analyses. Utilizing proxy information can be quite competitive and more efficient than other incomplete analytical methods without proxy, but only when the proxy and the observed data share a common covariance matrix. Proxy information loses its value when it is highly variable as compared to the actual observed data. We suggest that detailed exploratory data analyses are necessary before deciding to incorporate proxy information in the analysis. If the proxy and actual data are similar in their variability, incorporating them in the analysis is efficient while controlling its bias. It is also beneficial from a design point of view. However, when the proxy data are highly variable compared to the actual observed data, we recommend that investigators discard the proxy data and use the traditional strategies of incomplete data analysis methods.

Abstract

In this entry we discuss the merits and drawbacks of available small sample approaches with approximately normally distributed repeated measures of data with missing values. This discussion is limited to cases where the missing data occurs on the outcome variable.

INTRODUCTION

The missing data problem, which persists in much of empirical scientific investigations, is particularly common in repeated measures data. One reason for this is that the same subjects are used repeatedly over time. One of the main goals in dealing with missing data is to try to remove biases and reduce the estimation variances in an attempt to improve the overall estimation efficiency, thereby increasing study power. With current advancements in computer technology, many computational analysis methods have been developed, but most have a major drawback: they rely heavily on large sample theory.^[1-3]

In their overview of missing data methods for approximately normally distributed repeated measures data in small samples, Carrière et al.^[4] discuss non-iterative procedures for data with compound symmetry and unstructured covariance matrices, as well as the use of proxy information. In general, the approach to incomplete data involves identifying appropriate missing data mechanisms.

In this work, which supplements the previous work done by Carrière et al.,^[4] we discuss the merits and drawbacks of available small sample approaches with approximately normally distributed repeated measures data with missing values. This discussion is limited to cases where the missing data occurs on the outcome variable. In particular, this entry expands the discussion to include multiple imputation approaches. We use a numerical example to demonstrate the practical implications.

MISSING DATA MECHANISMS AND IMPLICATIONS

Most missing data methods are based on an assumption that missingness indicators contain true values that are meaningful for analysis.^[5] Therefore, we must make an effort to reveal the true values. Obviously, procedures based only on the complete subset data can create serious biases and result in inefficient analyses.^[1, 5]

We consider repeated measures data y_{ij} for subject $j = 1, \dots, N$ in period $i = 1, \dots, p$ in the presence of treatment effects, along with a covariate or design vector x_{ij} with $m_{ij} = 0$ if y_{ij} is missing and 1 if y_{ij} is observed. The goal is to efficiently estimate the contrast of treatment effects in the presence of missing values.

Little and Rubin^[5] define three unique of types missing data mechanisms that occur in different situations: missing completely at random (MCAR), missing at random (MAR), and nonignorable missing (NIM). In the MCAR situation, cases with complete data are indistinguishable from cases with incomplete data, so that $E(y_{ij} | m_{ij} = 1) = E(y_{ij} | m_{ij} = 0)$. Also, we have $p(m_{ij} = 1 | x_{ij}, y_{ij}) = p(m_{ij} = 1)$. This implies that the investigator can get consistent results by examining only the complete subset data. There is no danger of biased estimation, whether or not incomplete pairs receive appropriate attention. However, data can be missing for uncontrolled events in the course of data collection, and missing data are often associated with study variables—both the outcome and the covariates. The MCAR is too strong an assumption in reality.

In the MAR situation, cases with incomplete data differ from cases with complete data. The probability of observing a missing value depends on the observed values, but not on the unobserved values (both the covariates and outcome). Here, we have $E(y_{ij} | x_{ij}, m_{ij} = 1) = E(y_{ij} | x_{ij}, m_{ij} = 0)$ and within some subclasses of the data, they are still a random sample of cases.^[5] Therefore, missing values are traceable or predictable from other variables available in the database already observed. Investigators have approached this situation in a variety of ways, including imputation,^[6–11] weighting,^[5,12,13] resampling methods,^[7,14] data augmentation,^[15] and the Gibbs sampler.^[16] The success of these techniques depends on correctly specifying the missingness mechanism and/or the imputation model. Rubin and Little^[5] show that, in the case of MAR data, the likelihood inference produces consistent and efficient results even if the missing data mechanism is ignored. In the context of a generalized estimating equations approach, Liang and Zeger^[17] have found that the normal-model GEE is consistent when the missing data depend on any number of previous observations (i.e., MAR), if the mean function is correctly specified. It appears that both the bias and the standard error of estimates can be reduced as long as all available cases are used for both MCAR and MAR data, especially when using likelihood-based methods.^[5] Little^[10] and Park and Lee^[18,19] advocated simple pattern mixture models to test the dependence of responses on the missing data mechanisms, assuming that the missing data are ignorable. If the test is rejected, the missing data are determined not to be of type MCAR, but MAR.

In the NIM situation, the missing data mechanism is not completely random (non-MCAR), nor is it predictable from other variables in the database (non-MAR). Here, the reason for the missing data is explainable, but unmeasurable, because the very variable causing the data to be missing is unobservable.^[5] For valid analysis results, it is important to handle nonignorable missing data appropriately. Imputation, or a sampling-importance resampling approach, has been used to achieve the desired efficiency and unbiased analysis.^[12] Sheng and Carrière^[14] conclude that, in item response data analysis, the bootstrap under imputation approach can accommodate all missing data mechanisms, including the NIM situation, efficiently and without bias. However, this procedure is based on large sample theory.

In summary, consistent and efficient analysis depends on the investigator's ability to choose an appropriate missing data mechanism. It is especially important to devise a model for the nonignorable missing values, which accommodates a particular situation. Since any model for nonignorable data is specific to a given study and cannot be discussed in general terms, we have limited this discussion to MAR and MCAR situations.

AVAILABLE DATA ANALYSIS

Many investigators developed methods to utilize all available data rather than discarding incomplete pairs. Little and Rubin^[5] noted that available case analysis methods generally lack practical appeal due to the imbalance problem of varying sample bases. When the sample bases vary from one variable to another variable within a study, obtaining estimates of the parameters, or even asymptotic standard errors, can become very complicated. However, this is not an issue when using the ML method under an MCAR or MAR missing data mechanism with large samples, as there are valid standard errors and tests available based on large sample theory.^[3] For small sample cases, though, further work is still needed. Several studies, although limited in scope, have indicated that the available case analysis method is superior to complete subset analysis.^[1,2,20]

Approximate inference procedures have also been proposed for small samples to utilize all available data, if not all available cases. Carrière et al.^[4] present an overview of missing data strategies, with a focus on available data analysis methods for approximately normal repeated measures data. Their concern is with small sample data, and they discuss approximate distributions of estimators for making inferences for parameters of interest.

In particular, Carrière^[1,2] has developed small sample testing procedures based on the maximum likelihood method for two particular situations of the within-subject covariance matrix—when it has a compound symmetry pattern and when it is unstructured. Approximate solutions for small sample inference procedure were found upon obtaining the explicit forms of the standard errors of the parameter estimators of interest. Carrière^[1,2] also suggested an approximate degrees of freedom approach based on the Satterthwaite^[21] approximation method and on the assumption that the variability of higher-order terms is negligible. Although rather complex, these methods have been demonstrated to work well in computer simulation studies.

Other small sample available data analysis methods can also be applicable when using common software (for example, PROC MIXED in SAS^[22]), with approximation techniques similar to those suggested by Carrière,^[1,2] but based on different assumptions. Comparing her procedure with the SAS procedure, Carrière^[1] noted that the inference based on the available data method depends on the design structure. PROC MIXED in SAS approximates the distribution of the estimators uniformly to make inferences for all model parameters. It appears that caution is advised if the design is not orthogonal, as the analysis results can be more liberal or more conservative than expected.^[1]

Although the Carrière procedure^[1,2] can generally apply to any repeated measures data with missing values occurring monotonically and at random, the estimation methods are applicable to only two, very specific cases.

The procedure can be extended to other forms of covariance structures in an attempt to obtain approximate or even asymptotic distributions of the estimators. But because of the complexity involved, it may not be practical or even possible to use the procedure without making many unrealistic assumptions. For this reason, we echo Little and Rubin^[5] who concluded that the current state of available data/case analysis is not generally satisfactory for small sample repeated measures data. Further development is needed.

IMPUTATIONS

Imputations (both single and multiple) require creating a predictive distribution based on the observed data, either implicitly or explicitly.^[9] Examples include mean, regression, stochastic regression, hot or cold deck imputations, and substitutions. Composite methods combining some of these imputations and other techniques can also be used. Typically, imputation builds on the conditional mean of the missing outcome given observed data. Practically, imputation approaches are attractive because of their easy implementation and computational convenience, because the data are completely filled in even if the values are artificial, and the pseudocomplete data can be analyzed using standard software.

Single Imputations

Single imputation approaches impute a single data point for each missing value. Single imputations were used in empirical research even before the theory had been formally developed. Using imputation approaches for each draw of the data, a complete data set $\mathbf{y} = (\mathbf{y}_{\text{obs}}, \mathbf{y}'_{\text{mis}})$ is obtained by combining the observed data set $\mathbf{y}_{\text{obs}}$ and the imputed data set for the missing values $\mathbf{y}'_{\text{mis}}$. The most popular of these single imputations is probably the mean substitution based on a specific covariate pattern. See Rubin^[9] for details.

From a slightly different perspective, Huang et al.^[23] discussed a single imputation strategy where the imputation uses proxy information from caregivers or family members of a respondent who can provide approximate information on behalf of the respondents. Then, this proxy information can be used for analysis instead of dealing with missing responses. The principal idea of this approach is implicit, in that it assumes an underlying model where the respondents and their proxies share a common mean and variance. Possible differences in the mean and variance can be accommodated. Huang et al.^[23] also provided an approximate degrees of freedom solution to the testing hypothesis problem for missing repeated measures data with proxy.

Huang et al.^[23] reported that a single imputation with proxy information can play a significant role in missing data analyses. They also discussed design implications in

order to provide general guidelines for utilizing available proxy information to improve data collection strategy for missing data situations. However, when the variability between the actual and proxy data sets is different, it is better to use other available case analyses so as to maintain the type I error rate and to increase the power of testing parameters of interest.

Multiple Imputations

In the multiple imputation strategy, which was first proposed by Rubin,^[8] the imputed values are supposed to represent repeated random draws under a given model for each missing value. Overall inferences can then be drawn by combining results from complete data sets.

Multiple imputation involves drawing multiple values for each missing data point and there are various methods available for drawing the values to impute.^[9] For each draw of the data under a chosen imputation method, a complete data set $\mathbf{y}^m = (\mathbf{y}_{\text{obs}}, \mathbf{y}^m_{\text{mis}})$ is created by combining $\mathbf{y}_{\text{obs}}$ and $\mathbf{y}^m_{\text{mis}}$, $m = 1, \dots, M$, as defined earlier. Substantial empirical work^[24–26] has shown that multiple imputation with $M = 3$ or 5 works well with typical fractions (<30%) of missing data in surveys. Rubin^[9] suggests using standard inference methods to analyze each of the complete data sets $\mathbf{y}^m$ and then combining them for overall analysis results. In this section, we discuss the imputation strategy for repeated measures data. We assume that missing data occur monotonically, so that the data can be clustered into L groups according to the number of periods the subjects completed. Carrière^[1] has noted that some intermediate missing values, which are frequently few in number, can be imputed or removed before proceeding with the analysis, without much loss of information.

Let $\mathbf{y}_j = (y_{1j}, \dots, y_{pj})^T$ be the vector of responses from subject j where y_{ij} is from subject j in period i , $i = 1, \dots, p$ and $j = 1, \dots, N$. We can express the data from this repeated measurement design by the model

$$\mathbf{y}_j = \boldsymbol{\mu}_j + \boldsymbol{\varepsilon}_j = \mathbf{x}_j \boldsymbol{\beta} + \boldsymbol{\varepsilon}_j \quad (1)$$

for a $q \times 1$ vector of parameters $\boldsymbol{\beta}$ linking responses to some design or covariate matrix $\mathbf{x}$.

Richardson and Flack^[3] propose a multiple imputation strategy for analyzing the data based on regression models. Called the residual draw (RD) method, this approach is based on Rubin^[9] and is specific to three-period crossover trial data. The RD method imputes the conditional predictive mean of the incomplete case with additional noise. Basically, the investigator draws noise from the empirical distribution, and is therefore less sensitive to violations of the normal assumption.

The RD method is implemented separately for each group/sequence. It involves estimating the least squares estimators to fit a regression of the observed $(p + 1)$ th

period data on the observed first p periods data to obtain $\hat{\beta}$ for each regression model. Then, the error variance is set as $\sigma^{*2} = \text{SSE}/W$ where SSE is the residual sum of squares from the least squares fit and W is a draw from a chi-square distribution with the degrees of freedom of SSE. Then, a β^* is drawn from the $N(\hat{\beta}, \sigma^{*2}(x^T x)^{-1})$. Finally, to impute for an incomplete case i , the method imputes a value $Y_i^* = x_i^T \beta^* + r_0^* = Y_0 + (x_i^T - x_0^T) \beta^*$ where those with a subscript 0 are data values observed for a complete case drawn at random from the subjects in the given sequence. The r_0^* is the residual of that case when $\beta = \beta^*$. Through simulations, Richardson and Flack^[3] show that their strategy works well. However, their simulation uses relatively large sample data.

Huang and Carrière^[27] suggest that a less parametric approach than the one proposed by Richardson and Flack would be more robust. They impute the missing values using conditional distribution of the missing data, given the observed data in previous periods. The p_1 -vector $y_{(p_1)j}^T = (y_{1j}, \dots, y_{p_1j})$ for the complete subset data up to the first p_1 periods is assumed to be distributed as multivariate normal with mean $\mu_{(p_1)}^T = (\mu_1, \dots, \mu_{p_1})$ and covariance matrix Σ_{11} , the $p_1 \times p_1$ subcovariance matrix for the first p_1 periods. Then, the conditional distribution of $y_{p_1+1,j}$ given $y_{(p_1)j}$ is normal with mean $\mu_{p_1+1} + \sigma_{21} \Sigma_{11}^{-1} (y_{(p_1)j} - \mu_{(p_1)})$, and variance $\sigma_{22} - \sigma_{21} \Sigma_{11}^{-1} \sigma_{12}$, where Σ_{11} is the submatrix of Σ for the first p_1 rows and p_1 columns, σ_{21} is that for the $(p_1 + 1)$ th row and the first p_1 columns, with $\sigma_{12} = \sigma_{21}^T$, and σ_{22} is the $(p_1 + 1)$ th diagonal element of Σ . For subsequent periods, replace p_1 with $p_1 + 1$, and repeat the process. See also Carrière.^[2] Since the covariance matrix is usually unknown, the investigator uses the respective sample estimates, obtained based on complete subsets of the data and denoted by s_{ij} , s_{ij} , and S_{ij} . Then, Huang and Carrière^[27] extended the imputation strategy that Rubin^[9] suggested for a univariate normal model to a multivariate normal model.

This strategy involves estimating the conditional mean $\hat{\mu}_{p_1+1} = \bar{y}_{p_1+1} + s_{21} S_{11}^{-1} (y_{(p_1)j} - \bar{y}_{(p_1)})$, and the variance $\hat{\sigma}^2 = s_{22} - s_{21} S_{11}^{-1} s_{12}$. then, the conditional estimators are updated by drawing a chi-square random variable g with degrees of freedom $N^{(l)} - s$ and a random variable from a standard normal distribution z as $\sigma^* = \hat{\sigma} (N^{(l)} - s)/g$ and $\mu_{p_1+1}^* = \hat{\mu}_{p_1+1} + \sigma^* z / \sqrt{N^{(l)}}$, where $N^{(l)}$ is the total number of observations at the missing data stage l and s is the number of sequences. Then, a random variable z is drawn from a standard normal distribution to impute for the missing values in the period $p_1 + 1$, as $y_{p_1+1,j} = \mu_{p_1+1}^* + \sigma^* z$. This is repeated for all missing components in the period $p_1 + 1$. Treating the imputed values as if they were actual values, the steps are repeated for the next periods, with p_1 replaced by $p_1 + 1$. This whole process is repeated M times to create M multiply imputed data sets.

The multiply imputed data sets are analyzed to obtain an overall result. First, the usual data analysis is performed for

each of the M imputed data sets. The M analysis results are then combined to give a repeated-imputation inference as follows. Let $\hat{\beta}_m$ and W_m be the estimators and their associated variance-covariance matrix for β from the complete data set m , $m = 1, \dots, M$. The overall estimator of β from M data sets is obtained from $\bar{\beta}_M = \sum_{m=1}^M \hat{\beta}_m / M$ and its variance as $V(\bar{\beta}_M) = T_M = \bar{W}_M + (1 + M^{-1}) B_M$. The M within-imputation variances W_m are averaged to obtain $\bar{W}_M = \sum_{m=1}^M W_m / M$, and $B_M = \sum_{m=1}^M (\hat{\beta}_m - \bar{\beta}_M)(\hat{\beta}_m - \bar{\beta}_M)^T / (M - 1)$ is the between-imputation variance.

To test a hypothesis of a linear contrast $\theta = l^T \beta$, Rubin^[9] considers an approximate distribution for θ given by

$$(\theta - \bar{\theta}_M) [l^T T_M l]^{-1/2} \sim t_v \quad (2)$$

where $\bar{\theta}_M = l^T \bar{\beta}_M$, and the degree of freedom v is

$$\tilde{v} = v_0 \{ [f(v_0)(1 - r_M)]^{-1} + v_0 / v \}^{-1} \quad (3)$$

where $f(v_0) = (v_0 + 1) / (v_0 + 3)$, $r_M = (1 + M^{-1}) \text{tr}(B_M T_M^{-1}) / q$, and v_0 is the degree of freedom based on the complete subset data. The r_M estimates the fraction of information on β that is missing due to nonresponses. This fraction can be no larger than that of all missing data.^[9]

IMPUTATION OR AVAILABLE CASE ANALYSIS?

The available data analysis method is not always satisfactory for the reasons stated in the section Available Data Analysis above. Then, the imputation approach might be one alternate method to use. There are others, but most of them build on simulation methods (for example, data augmentation^[15] and Gibbs sampler^[16]). This entry compares available data analysis methods and imputations, among other possible approaches.

Many investigators favor multiple imputations over single imputations because they can generate random variations in imputed artificial data. However, many studies have also found that this method does not perform as effectively as expected. For example, in the context of generalized linear models, Xie and Paik^[13] considered four multiple imputation strategies and sample average imputations. They conclude that as long as one uses all available data, all approaches are consistent and efficient. For continuous responses, Huang and Carrière^[27] found that there is no real advantage in creating multiple complete data sets, as the analysis method that uses only available data performs as well as or better than the multiple imputation method.

Specifically, Huang and Carrière^[27] note that the corresponding asymptotic distributions appear to fit reasonably well for the two approaches they considered (ML and MI approaches) as long as all available data are used. In that study, the multiple imputation method performed as well as

the ML method^[1,2] for all situations considered. However, the ML method was found generally superior to the multiple imputation method, especially when the correlation is large and the covariance structure is unspecified.

In light of the technical limitations noted earlier regarding the available data method, Huang and Carrière^[27] suggest adopting the multiple imputation method when types of covariance structures other than compound symmetry or unstructured covariance matrices provide a good fit to the data in small samples. Although their implementation of the multiple imputation method for small samples was not entirely satisfactory in terms of keeping the type I error and testing power, they recommended that the violation may be far less serious than that by the ML approach with large sample theory assumptions. Also, it could be considerably more complicated to try to calculate the asymptotic standard error of the ML estimators than using multiple imputations. See also Richardson and Flack.^[3]

As noted in the previous section, the real advantage of using multiple imputations is not in obtaining efficient estimators, but in obtaining unbiased estimators for parameters by attempting to reveal the true values for missing data. However, the one advantage of the multiple imputation (and of any other imputation techniques) is its capacity to use standard analysis statistical software. As long as all available data are used, both ML and MI approaches seem to be valid for univariate data as well as for repeated measures data analyses. Further work needs to be done on deriving the asymptotic small sample procedures for available data analysis. Also, there is a need to investigate the sample sizes required for the asymptotic ML procedures that can be validly used with standard software.

This study has not dealt with the NIM case. We suggest that the alternative imputation strategy using proxy information, as in Huang et al.,^[23] could be effective. This approach would likely work if proxy providers carefully

assess reasonable responses from the respondents with a full understanding of the reasons for the missing data in the given situation.

ANALYSIS OF BRONCHIAL ASTHMA DATA

To contrast the methods discussed in this paper, we analyzed the bronchial asthma data in Patel,^[28] which utilizes the traditional two-period, two-treatment, two-sequence design with eight and nine patients in each sequence, respectively, and $N = 17$. We conducted an exploratory data analysis to determine the covariance structure, and we observed the compound symmetry covariance structure to provide an adequate fit to the data.

We analyzed the original complete data using PROC MIXED in SAS, and compared the (exact) test for the treatment and carryover effects to the t distribution with the degrees of freedom computed from $(N - 2) = 15$ from the complete actual data. Grizzle^[29] suggested a two-stage analysis for assessing the significance of the residual effects, using a P -value of 0.15 to determine insignificance of a residual effect. Based on the two-stage analysis, we did not remove the residual effect, and thus concluded that, in the presence of a nonnegligible residual effect, the test of a direct treatment effect was significant at 0.05 (first row of Table 1).

Next, we induced missing values by deleting the measurements in the second period from the four subjects in the BA treatment sequence to produce MAR data. We then compared the analysis based on the complete subset data omitting both measurements from the four subjects with missing observations in the second period to t distribution, with the exact degrees of freedom computed from the complete subset data of $17 - 4 = 13$ patients (second row of Table 1). The results are similar to the original data analysis, with a slightly lower estimate for the treatment effect

Table 1 Analysis Results of Bronchial Asthma Data

^dMethod by PROC MIXED of SAS with df adjustment of Huang et al.^[23]

^eMultiple imputation method by Huang and Carrière.^[27]

and a higher estimate for the residual effect, but higher standard errors for both.

Applying the available case analysis method of Carrière,^[1] the tests are compared against t_{11} , the approximate degrees of freedom of $(N^{(2)} - 2)$, where $N^{(2)}$ is the number of subjects with complete observations. We obtained results similar to the original data analysis (third row of Table 1). We see improved power over the complete subset analysis. A slightly different approximation procedure by SAS PROC MIXED produced results similar to complete subset analysis (fourth row of Table 1). In particular, the residual effect is now insignificant according to Grizzle.^[29] Some comparisons of these two available case methods can be found in Carrière.^[1]

Applying the single imputation approach of Huang et al.,^[23] we considered: (1) choosing values close to their first period values, taking into account that they tend to be smaller in period 2 than in period 1 (*proxy I* = 2.5, 1.5, 3.0, 1.0 and (2) slightly overestimating the missing data (*proxy II* = 3.0, 2.0, 3.5, 1.25). We first examined the bias and possible variance heterogeneity of the proxy data from the actual responses. The variances of the proxy data sets are a little larger than those of the actual data, but the test of a common variance is not rejected. Hence, the tests are compared against t_{13} , with approximate degrees of freedom of $(N - 4)$, assuming a common variance between proxy and the real data. Rows 5 and 6 in Table 1 show the results of the analysis described in Huang et al.,^[23] and rows 7 and 8 show those using SAS PROC MIXED. When using PROC MIXED, we adjusted the degrees of freedom as suggested by Huang et al.^[23] These proxy approaches reflected the mechanism used in choosing the proxy values with slightly less sensitive results in the proxy II than in proxy I, and an indication that the residual effects are non-existent. Huang et al.^[23] note that tests of treatment effects are affected by the presence of proxy data, resulting in a less sensitive outcome than for nonproxy approaches in this case. However, if we remove the insignificant residual effects from the model, we reject the null hypothesis of equal treatment effects in all cases, and conclude that the treatment effects are significantly different, as in the analysis of full original data.

Finally, we applied the non-regression-based multiple imputation approach of Huang and Carrière.^[27] The results are reported in row 9 of Table 1. The advantage of this approach is the convenience of using any standard software of choice for the analysis, but the penalty is quite high, as reflected in the adjusted degrees of freedom. The qualitative results are similar to those from the original data analysis and the available case analysis (see rows 1 and 3).

CONCLUSIONS

The purpose of this entry is twofold: the first is to supplement the Carrière et al.^[4] by including the imputation

procedure for small sample repeated measures data and the second is to compare implications of various incomplete data methods. Available data analyses are said to be generally unsatisfactory, because the calculation of the asymptotic standard errors of estimators is quite complex even for MCAR. However, when available, they are found to be more powerful than multiple imputations. Imputation-based procedures fill in for the missing values to analyze them by standard methods. When desired, the strategy of the multiple imputation method discussed by Huang and Carrière^[27] may be used for small sample repeated measures data; its overall performance was not substantially worse than that of the alternative. The discussion was limited to the MCAR and MAR cases and future work dealing with the NIM case will be forthcoming.

Reproductive and Developmental Studies

James J. Chen

U.S. Food and Drug Administration, Jefferson, Arkansas, U.S.A.

Abstract

The ultimate goal of reproductive and developmental studies is to assess reproductive risk to mature adults and risk to the developing individual at all stages from exposure to drugs and environmental compounds. This entry discusses statistical design methods and analysis and touches briefly on regulatory requirements in reproductive and developmental studies.

INTRODUCTION

Soon after the thalidomide tragedy in the late 1950s and early 1960s, which resulted in over 8000 malformed babies, there has been a great deal of interest in predictive tests of reproductive and developmental effects. The ultimate goal of the studies is to assess reproductive risk to mature adults and risk to the developing individual at all stages—from conception to sexual maturity, and from exposure to drugs and environmental compounds. Adverse reproductive and developmental effects include effects on male and female fecundity, spontaneous abortion, infant and child death, congenital malformations, growth retardation, and mental retardation. Some compounds may cause rather specific adverse effects, while others may have a broad spectrum of disturbance to the embryonic and fetal development resulting in all types of adverse effects.

Human data provide the most appropriate information for determining potential adverse effects of a compound. Human studies include epidemiologic studies and case reports. There are several types of epidemiologic studies; each has certain advantages and limitations. Cohort studies compare the results of clinical endpoints between exposed groups and unexposed groups to establish an association between a specific exposure and the outcome. Case-control studies compare the individuals with a particular disease to similar but nondiseased individuals on their exposure history, retrospectively. Because of ethical and practical considerations, dosing in humans to study adverse effects is excluded. Useful information for assessing human risks may be derived from human studies with adequate design and statistical power. However, the information for potential effects on humans is generally obtained using laboratory animal experimental models. Substantial evidence indicates that agents which have been associated with human effects can also be associated with adverse effects in animals.

The views presented in this paper are those of the author and do not necessarily represent those of the U.S. Food and Drug Administration.

Reproductive Studies

Reproductive studies evaluate the potential adverse effects of test compounds on reproductive systems of both adult males and females as well as the on the postnatal maturation and reproductive capacity of the offspring, and the cumulative effects on generations. The studies are designed to evaluate: (1) the effects on male and female fertility; (2) the effects during gestation on the mother and on the fetus; (3) the effects appearing after parturition on mother's lactation and on offspring growth, development, and sexual maturation; and (4) the mutagenic effects through several generations.

Developmental Studies

Developmental studies evaluate the effects of test compounds on a developing organism that result from the exposure of parent(s), during perinatal development, or from postnatal development to the time of sexual maturation. The studies are designed to evaluate: (1) the death of the developing organism, (2) structural malformations and variations, (3) altered growth, and (4) functional impairment.

REGULATORY REQUIREMENTS

The U.S. Food and Drug Administration (FDA) and other countries require that new drugs and certain medical devices must be approved for safety and effectiveness for their intended use before being marketed. Food additives, color additives, compounds for use in food-producing animals, and pesticide residues in foods must be shown to be safe for the proposed use. In 1966, the U.S. FDA^[1] published guidelines for the performance of reproductive and developmental tests of drugs in animals. Three segments of study are required in preclinical animal testing for each new drug depending on how women might be exposed to the

drug. These are referred to as Segment I (fertility and general reproductive performance), Segment II (developmental effects), and Segment III (perinatal and postnatal evaluations). These studies may be run more or less concurrently, and may be run in conjunction with chronic tests.

Three-Segment Design

The Segment I study is aimed at providing an overall evaluation of the effects of drugs on fertility in both sexes, the course of gestation, early and late stages of the development of the embryo and fetus, and postnatal development. The studies may be conducted by treating animals of only one sex and by mating with untreated animals of the opposite sex, or by treating both male and female animals. Segment II is primarily aimed at detecting teratogenic effects. The drug is given to the pregnant females during the period of organogenesis (e.g., days 6–15 for rats and mice, and days 6–18 for rabbits). The offspring are removed 1 or 2 days before term, and the corpora lutea, resorption sites, and live and dead fetuses are examined. Fetuses are weighed and examined for anomalies. Segment III is aimed at the evaluation the effects of drugs on the late stages of gestation and on parturition and lactation. The drug is given to pregnant females in the final one-third of gestation and continued throughout lactation to weaning (e.g., gestation day 15 to postnatal day 21 for rats or mice). The effects on duration of gestation are determined. Pup birth and developmental data including litter size, weight, and postnatal growth and mortality, along with impaired maternal behavior, are recorded and measured.

Most countries adopted the general principle of requiring the three segments of investigations in the preclinical testing of new drugs. Recently, the International Conference on Harmonization (ICH), representing the United States, the European Community, and Japan, published guidelines to address uniformity in conducting Segment I, II, and III studies.^[2–4] The ICH guidelines allow a standardization of protocols and a deletion of duplication of procedures with emphasis on flexibility in testing strategy. Testing for food additives, color additives, and animal drugs requires a Segment II developmental study with the incorporation of multigeneration reproductive studies.^[5–8] Testing requirements for environmental agents such as pesticides and industrial chemicals, regulated by the U.S. Environmental Protection Agency,^[9,10] are similar to those for food additives; that is, a standard Segment II developmental study and two-generation reproductive studies are required. In general, testing protocols for pharmaceutical and nonpharmaceutical chemicals are similar; however, the data for nonpharmaceutical chemicals would be used to establish an acceptable level of exposure using quantitative risk assessment.

When a drug has been approved for marketing by the FDA, the information for the safe and effective use of the drug must be on the label. The FDA^[11] published a

uniform labeling format for human prescription drugs. The pregnancy labeling provides information with regard to use during pregnancy for all drugs. The FDA has devised five categories to describe levels of potential risk to human pregnancy based on findings from animal and human studies.^[11,12] Category A is to be used for drugs where adequate, well-controlled studies in pregnant women have failed to demonstrate risk to fetus. Category B is used for those drugs for which no controlled studies have been conducted in human pregnancy, and animal studies have not indicated the potential for human developmental risk. Alternatively, animal studies may indicate some risk but controlled human studies do not. Category C is used for drugs where there are no controlled studies in human pregnancy and animal studies demonstrate an adverse effect, or have not been conducted. Potential benefits, however, may justify the potential risks. Category D is for drugs where there is a positive evidence of human developmental risks. Investigational and postmarketing surveillance data may show human developmental risks, but potential benefits may outweigh the human risks. Category X is used for agents where there is a documented evidence of human development toxicity from reports in the literature or postmarketing surveillance. The risk to human conceptus is considered to outweigh any possible benefit.

STATISTICAL DESIGN/METHOD/ANALYSIS

Experimental Design

Mice, rats, and rabbits are the most commonly used species for reproductive and developmental studies. The various guidelines generally require testing in a rodent and nonrodent species, usually rats and rabbits. An experiment typically consists of an untreated control and three dose groups. The highest dose is chosen to produce minimal maternal toxicity, ranging from marginal body weight reduction to not more than 10% mortality. The low dose should be a no-observed-adverse-effect level for both maternal and developmental toxicity. The midlevel dose usually is halfway between the low dose and the high dose. A fourth dose group may be added to avoid excessive dosage intervals and to assess dose–response relationships. Sometimes doses are based on known or expected human therapeutic or toxic levels. Typically, dosage is measured in milligrams per kilogram body weight per day. The U.S. regulatory guidelines generally recommend about 20 pregnant rodents and 15 nonrodent animals per dosage group. The ICH guideline recommends the use of 16–20 pregnant animals. Typical litter sizes (number of viable offspring) for the control animals range from 8 for rabbit to 12 and 14 for mice and rats, respectively.

Depending on the design, a test compound is administered to either parent prior to conception, and to the female

during prenatal development, and postnatally. Animals can be assigned to dose groups totally randomly or be assigned by stratified body weight (but randomly within body weight classes). Each animal is monitored throughout the experiment to detect toxic and pharmacologic effects of the test compounds. In a Segment II study, the pregnant dams normally are sacrificed just prior to term, and fetuses are then examined to assess developmental effects. In a Segment III study, females are allowed to deliver and rear their offspring. Postnatal functional evaluations are performed. All adult animals are necropsied at terminal sacrifice.^[3,13]

During the reproductive process, ovarian follicles release eggs, which are fertilized by sperms to form embryos. These embryos subsequently implant into the wall of the uterus. The discharged ovarian follicles differentiate into corpora lutea, which secrete hormones necessary to sustain pregnancy. The embryos undergo organogenesis to form fetuses. Each step in this process is a potential target for toxic effects of a test compound. Depending on when treatment begins, a test compound may affect the number of ovulating follicles, the number of corpora lutea, the number of embryos implanting into the wall of the uterus, or the number of live fetuses surviving to term. For surviving fetuses, growth retardation may occur, or fetuses may exhibit one or more types of structural malformations. Fig. 1 is a sketch of the outcomes from a dam in the developmental and reproductive toxicity experiment.

Regulatory requirements specify that a wide range of endpoints must be measured, recorded, and analyzed. The endpoints can be divided into two categories: parental and embryonic/fetal endpoints. Parental endpoints to assess the reproductive effect include: body weight

and weight gain, mating index, fertility index, changes in gestation length, sperm count, numbers of corpora lutea, implantation sites, dead or resorbed implants, viable fetuses, and target organ weights, as well as food and water consumption. Embryonic/fetal endpoints include: individual malformations (external or gross, visceral, and skeletal) and variations in viable fetuses, number of normal fetuses, fetal weight, fetal length, sex ratio, preweaning and postweaning survival and body weight, physical development, and functional tests.^[2,3,9,10,13]

Experimental Unit

In the analysis of animal developmental endpoints, the experimental unit is the entire litter rather than an individual fetus. In the experiment, the test compound is administered to the adult animal; the primary variables of interest are fetal responses. The effect of the test compound occurs in the female that receives the compound, or that is mated to a male that receives the compound. The treatment affects the fetuses indirectly via the dam. Thus the development of individual fetuses in a dam is not independent. The fetal responses from the same dam are expected to be more alike than responses from different dams. This phenomenon is referred to as the “litter effect.” The proper experimental unit in the analysis should be the litter with the fetal responses representing multiple observations from a single experimental unit. The failure to account for the intralitter correlations by using each fetus as the experimental unit will inflate the Type I error and will reduce the validity of the test.

Sample Size

Sample size determination is an important issue in detecting a dose effect. The probability of detecting a statistically significant effect increases with the increased magnitude of effect and the increased sample size. It is customary to specify a range of the magnitudes of the effect of interest; an optimal sample size then can be calculated to provide a reasonable power of detecting the effect. Sample size calculations and references for various tests are provided in Desu and Raghavarao.^[14] It should be emphasized that sample size determination is preferable to arbitrary requirements of testing 10 or 20 animals, as indicated in various guidelines for assessing reproductive and developmental effects.

Statistical Analysis

Statistical analyses of various endpoints are composed of two aspects: qualitative testing for adverse effects and quantitative estimation for risk assessment. The qualitative testing is used to determine if there is a statistically significant difference among the groups. Three statistical tests are conducted: (1) an overall test for significant differences

Fig. 1 Schematic representation of Segment I, II, III Studies

among groups, (2) pairwise comparisons between two specific groups (usually control vs. a dose group), and (3) a trend test to identify a dose-related increase or decrease. The trend test is more sensitive (powerful) to detect dose effect than the pairwise comparisons because it uses information from all dose groups. The quantitative estimation is used to determine a safe human level of exposure from an assessment of the dose–response relationship. The quantitative risk estimation typically does not apply to pharmaceutical drugs.

Methods

Endpoints are typically measured according to one of the three scales: continuous, count, and quantal (binary). Histological data such as severity or levels of achievement scores in behavioral testing may be recorded on the ordinal scale. Statistical methods appropriate for these different types of data are discussed separately.

Continuous Data

Continuous data such as body weights, organ weights, or behavioral measurements conducted on offspring following birth are measured on a continuous scale. The continuous endpoints are measured either at the litter level in an adult animal (e.g., maternal body weights) or at the individual fetus level (fetal body weights). Analysis of variance (ANOVA) is the most commonly used procedure for analysis of continuous data.^[15,16] The ANOVA procedure is used to assess the overall significant difference among groups. The ANOVA method assumes that data are independently and normally distributed with homogeneous variance. The logarithmic, square root, and arc–sine transformations are often applied to satisfy the normality assumption and to stabilize the variance. A simple one-way ANOVA analysis is the comparison of maternal endpoints among groups. Developmental endpoints traditionally are analyzed similarly but in terms of the average within each litter—a litter-based analysis.^[17] Nonparametric methods are used when the assumption of normality fails. The nonparametric analysis is initiated by ranking all observations of the combined groups. The nonparametric method is then applied to ranked data. Further details may be found in general texts addressing nonparametric methods.^[18]

There are a wide variety of post hoc tests available for pairwise comparisons or trend analysis after finding a significant result in an ANOVA. Dunnett's test^[19] and Williams' test^[20] are the two mostly used tests for comparisons of each of the dose groups to the control. Williams' test assumes an increasing (decreasing) dose–response trend. When this assumption is valid, Williams' test is more powerful in detecting differences between control and the dose groups. The Duncan multiple range test^[21] and the Tukey studentized range test^[22] are two frequently used procedures for all possible pairwise comparisons. Linear

regression is the simplest method to assess dose–response trends. But contrast tests, with a proper choice of contrast coefficients, in conjunction with ANOVA, are more commonly used for the dose–response trend test. Other trend tests are Tukey's test,^[23] which has been proposed to identify the highest dose at which there is no statistically significant trend, and Bartholomew's test of ordered alternatives.^[24]

ANOVA is also used in more complex experiments involving crossed (e.g., dose levels, replicates) and nested (e.g., litter effects) factors. The repeated-measures ANOVA is often used for the analysis of postnatal behavioral data.^[25] Multivariate analysis of variance (MANOVA) is used for a simultaneous analysis of several endpoints including repeated-measures data.^[25,26] A general approach to modeling developmental data can be carried out in terms of a mixed-effects model. Dempster et al.^[27] proposed a normal mixed-effects model with two levels of variance, in which litter effect is modeled by a nested random factor and dose is modeled by a fixed factor, for analyzing fetal weights.

Count Data

A number of primary reproductive endpoints are measured in counts. In a dominant lethal assay, male mice are treated with a suspect mutagen, and then are mated with females. The numbers of corpora lutea, implantations, lives, and dead conceptuses are counted to assess reproductive effects of the test compound. Count data are often normalized by the square root transformation; the transformed data are then analyzed as continuous data using the parametric ANOVA methods. Count data can also be analyzed by nonparametric methods.

Count data are generally modeled by a Poisson distribution. The mean of a Poisson is often expressed as a log linear function of dose and other covariates in the Poisson regression analysis. The Wald test, score test, or likelihood ratio test is used for group comparisons and trend test.^[28] A common complication in the analysis of count data is that the observed variation exceeds or falls below the variation that is predicted from a Poisson model. The negative binomial (gamma Poisson) distribution is a generalization of the Poisson model to account for the extra variation. Parametric and quasi-likelihood analyses of reproductive data with extra Poisson variation are given by Chen.^[29]

Binary Data

The binary endpoints, as continuous endpoints, can be measured either at the parent level, such as success or failure of pregnancy, or at the individual fetal level, such as presence or absence of a particular malformation type. Statistical methods for the analysis of the prenatal and fetal responses are different.

Two common approaches for the analysis of prenatal binary endpoints are the asymptotic tests and exact tests

(permutation tests). Asymptotic tests include the Pearson chi-square test and likelihood ratio chi-square test for the comparisons of the incidence rates among several groups.^[30] A continuity correction is often applied if only two groups are compared. The Cochran–Armitage test is used to test for trend.^[31,32] The Fisher exact test is the best known permutation test for comparing two groups. The permutation test computes the values of a “proper test statistic” from the observed data for all permutations (sampling without replacement) under the null hypothesis. The observed p value can be obtained by comparing the value of the observed test statistic with the empirical distribution. Ciminera^[33] proposed a randomization test for dose–response trend. General computational algorithms and software to perform all possible permutations are given by Mehta et al.^[34]

Because the litter rather than the fetus is the basic experiment unit, the analysis of fetal endpoints should account for the litter effect. The general approach to the analysis of developmental binary endpoints is to consider the proportion per litter such as the proportion of live fetuses with a certain type of malformation. Two approaches are commonly used for the analysis of proportions: litter-based analysis and extra binomial modeling. Both approaches assume that the denominator (“litter size”) is fixed.

Litter-based analysis has been widely used in the analysis of developmental data. Typically, the proportions are transformed by an arc-sine transformation, and then the parametric ANOVA methods are used. The litter-based approach does not use the data effectively because it does not account for the litter size. For example, one of two is treated the same as 5 of 10. Extra binomial modeling has been an important development in the methodology for the analysis of developmental data. The beta-binomial model and quasi-likelihood method have been well studied for the analysis of developmental data.^[28,35,36] The mean of the proportion is often expressed in terms of a logistic function. The Wald test, score test, or likelihood ratio test is used for group comparisons and trend test in the analysis with the beta-binomial model. The parametric and quasi-likelihood analyses of Segment II developmental data have been given by Chen.^[29]

Analysis

The commonly used litter-based method is presented in the data analysis. A typical experiment consists of g groups, a control, and $g - 1$ dose groups. Assume that the i th group contains m_i female animals. Let y_{ijk} be the response from a fetus out of n_{ij} examined or tested for a particular developmental outcome, $1 \leq i \leq g$, $1 \leq j \leq m_i$, and $1 \leq k \leq n_{ij}$. Note that y_{ijk} may be an indicator variable representing the presence or absence of a particular malformation type or a continuous variable representing a fetal weight or postnatal performance measurement. Depending on the endpoint of interest, n_{ij} may represent the number of viable

fetuses, number of implants, or number of measurements. The litter-based analysis is based on the per-litter response $y_{ij} = \sum_k y_{ijk} / n_{ij}$. For a continuous response, y_{ij} will represent the mean fetus response; for a discrete variable, it will represent the sum of the fetal responses. The y_{ij} can be viewed and analyzed as a maternal endpoint.

A statistical analysis of a study of effects of maternal exposure to diethylhexyl phthalate (DEHP) in rats is presented here.^[37] Diethylhexyl phthalate was administered in the diet on gestational days 0 through 20 at 0.00%, 0.5%, 1.0%, 1.5%, and 2.0%. The study was conducted with two replicates. Approximately equal numbers of dams were assigned to each group, and gestational day 0 body weights were matched across dose within each replicate. At gestational day 20, animals were sacrificed and all fetuses were examined.

A two-way (dose $\times$ replicate) ANOVA model was used for the analysis of continuous endpoints or per-litter proportion data. Prior to analysis, the arc-sine square root transformation was performed to all maternal or per-litter proportion data. A test of linear dose–response trend was performed using contrast tests. When a significant ($p < 0.05$) dose effect occurred, Duncan’s multiple range test was used for pairwise comparisons between control and each dose group. A one-sided test was used for all pairwise comparisons except for the maternal and fetal body weights and percentage of males per litter. Nominal (incidence) data were analyzed by a chi-square test for differences among groups, and by a Cochran–Armitage linear trend test on proportions. A one-sided Fisher’s exact test was used for pairwise comparisons when the chi-square test was significant. Table 1 contains a summary of the analysis for selected endpoints. For a detailed analysis, the reader is referred to Tyl et al.^[38]

SCIENTIFIC ISSUES

The main objectives in the analysis of reproductive and developmental experimental data are group comparisons and dose–response modeling. The statistical analysis of developmental endpoints presents a number of important issues. Developmental endpoints consist of both continuous and discrete outcomes. The analysis needs to account for the correlations induced by the clustering effects within litters. Tests for group differences for continuous endpoints are commonly conducted using the ANOVA with litter nested, MANOVA, or mixed-effects models. In contrast to the multivariate normal distributions for multiple continuous outcomes, distributions for the analysis of multiple binary outcomes are modeled in terms of sums of correlated binary variables under the exchangeability assumption. The resulting distribution is a generalized binomial. The distribution for the common developmental endpoints, such as the number of malformations per litter, often has an overdispersed binomial, but the distribution of sex combinations can be an underdispersed binomial.^[39]

Table 1 Reproductive parameters after the exposure of pregnant Fisher 344 rats to DEHP in the feed on gestational days 0–20

Endpoint	DEHP percent in feed				
	0.0	0.5	1.0	1.5	2.0

^aSignificance in linear trend.^bSignificantly different from control.

The beta-binomial distribution includes a non-negative dispersion parameter to model intralitter variations. The beta-binomial model uses a full likelihood-based analysis. This model has disadvantages in that it does not allow for negative intralitter correlations, and its maximum likelihood estimates can be biased or numerically unstable.^[40,41] The quasi-likelihood method offers an alternative approach; the quasi-likelihood estimates are generally more stable than the beta-binomial maximum likelihood estimates. The quasi-likelihood approach does not provide inference on the dispersion parameter. Liang and Zeger^[42] proposed a general method for the analysis of correlated data. This method is often referred to as generalized estimating equation (GEE). The analysis of continuous as well as discrete developmental endpoints with the GEE approach has been described by Dempster et al.^[27]

In a typical reproductive and developmental study, various endpoints are collected in order to obtain the maximum information from the study. Statistical analysis often involves a large number of tests, both in terms of multiple comparisons among groups and multiple tests on many endpoints. Because of the conduct of a large number of statistical tests, the chance of false positive findings could increase considerably. Commonly, each endpoint is analyzed separately. A significant result for an endpoint tested may be statistical, biological, or both. The issues of false positive and false negative error rates in the testing

of multiple reproductive and developmental endpoints has not been addressed. The main consideration should be to maximize the power of identifying every significant endpoint while controlling the overall Type I or family-wise error rate.

CONCLUSION

Recently, several authors have proposed multivariate models for simultaneous analysis of multiple endpoints. Joint modeling of multiple developmental outcomes can have some advantages: It can increase the power of detecting effects if the multiple outcomes are manifestations of some common biological effect, and it allows investigations of associations among the multiple outcomes if they are the result of different biological mechanisms.

In the analysis of developmental data, two types of correlation are inherent: the (intralitter) correlation between fetuses of the same litter and the (intrafetus) correlation between the endpoints in the same fetus. A joint modeling of multiple binary outcomes of different malformation types has been proposed by Lefkopoulou et al.^[43] and Chen and Ahn.^[44] A joint modeling of two overdispersed binomial outcomes for the numbers of deaths/resorptions and malformations has also been proposed.^[45–48] Recently, several authors have proposed conditional approaches to modeling malformation and fetal weight.^[49–51] However, a joint

modeling of continuous and discrete outcomes within a cluster is not straightforward, and requires further research.

Likelihood-based and GEE approaches are developed for dose–response modeling of univariate or multivariate reproductive endpoints. The likelihood-based approach requires strong assumptions on the distribution and the variance–covariance structures. The maximum likelihood estimates may be computationally unstable. The GEE^[42] and GEE2^[52] methods can be used to estimate the mean and variance/covariance parameters. Examples of dose–response analysis of reproductive toxicity data using the GEE approach are given in Lefkopoulou et al.^[43] and Chen and Ahn.^[44] The software for the GEE method is commercially available.^[53,54]

Response Surface Methodology

William R. Myers

The Procter & Gamble Company, Mason, Ohio, U.S.A.

Abstract

Response surface methodology (RSM) is defined as a collection of mathematical and statistical methods that are used to develop, to improve, or to optimize a product or process. This entry works to provide a detailed definition of this type of methodology by presenting several design examples.

Keywords: Mathematical methods; Response surface methodology; Statistical methods.

INTRODUCTION

Response surface methodology (RSM) is defined as a collection of mathematical and statistical methods that are used to develop, to improve, or to optimize a product or process. It comprises of statistical experimental designs, regression modeling techniques, and optimization methods. Most applications of RSM involve experimental situations in which several independent variables (or factors) potentially influence one (or more) response variable. The independent variables are controlled by the experimenter, in a designed experiment, whereas the response variable is an observed output of the experiment. Fig. 1 illustrates the estimated relationship between a response variable and the two independent variables x_1 and x_2 .

In many applications of RSM, a sequential process is performed. At the start, a researcher may have numerous independent variables that are being studied. In order to determine which of the factors have an effect on the response variable, a *screening design* is often performed. This will potentially reduce the number of factors that need to be investigated in further experimentation. A researcher hopes to eliminate unimportant factors so that ensuing experiments (e.g., second-order response surface design) will be less costly and more efficient. In addition, an existing screening design could also be augmented with additional design points in order to estimate a second-order (or response surface) model. Another RSM tool is the *method of steepest ascent*. This is an optimization technique that will allow one to move iteratively toward an optimum set of experimental conditions. This is often implemented when the researcher is initially experimenting in a suboptimal region. It would not be very prudent to invest in a large—and perhaps costly—experiment unless one feels that the *region of optimum* is either inside the design region or very close to the periphery. After a *region of interest* has been defined, a response surface design is used to estimate a second-order model. This provides an approximation of

the true response surface over the region of interest, thus providing a better overall understanding of the estimated response surface and to determine the optimum operating conditions. RSM has been used extensively in many areas of biopharmaceutical research such as drug formulation, process development, and drug discovery. Many applications of RSM in biopharmaceutical research will be presented throughout the discussion.

MODEL BUILDING

A statistical model is used in order to estimate the relationship between the response variable and the independent variables. The estimated statistical model is called a *response surface model*. Regression techniques are used to estimate the response surface model. A first-order or second-order model is typically used to characterize this relationship. A first-order model assumes that each independent variable has a linear effect on the response variable. A first-order model is defined as: $Y = \beta_0 + \sum_{i=1}^k \beta_i x_i + \epsilon$ where Y is the response variable, β_0 is the model parameter that represents the intercept, β_i is the model parameter associated with the i th independent variable, x_i represents the level of the i th independent variable, and ϵ represents the random error. The parameter β_i represents the change in the response variable Y per unit change in x_i , while holding all the other variables constant. In many instances, an interaction between two independent variables is present. In those situations, the first-order model will include interaction terms as follows: $Y = \beta_0 + \sum_{i=1}^k \beta_i x_i + \sum_{ij} \beta_{ij} x_i x_j + \epsilon$ where β_{ij} is the model parameter that represents the interaction between the i th and the j th independent variable. When β_{ij} is present, the effect of the i th independent variable on the response variable Y depends on the level of the j th independent variable. The first-order model is typically used in cases where no curvature is present in the response surface, when the region of interest is narrow, or when the researcher

Fig. 1 An example of a response surface

attempts to reduce the number of factors for further experimentation through variable screening. In those cases where the aforementioned does not apply, a second-order model is commonly used. A second-order model assumes that the independent variables have a quadratic (or curvature) effect on the response variable. The second-order model is defined as $Y = \beta_0 + \sum_{i=1}^k \beta_i x_i + \sum_{i=1}^k \beta_{ii} x_i^2 + \sum_{ij} \beta_{ij} X_i X_j + \varepsilon$ where β_{ii} is the model parameter that represents the quadratic effect for the i th independent variable. The second-order model is extensively used in RSM. Myers, Montgomery, and Anderson-Cook^[1] point out that the second-order model is very flexible, in that it can approximate a variety of functional forms. Practical experience indicates that the second-order model works well in solving many real response surface problems.

The parameters for the previously discussed statistical models are estimated by the method of *ordinary least squares*. The parameter estimates are often called *regression coefficients*. Using matrix notation, the least squares estimator of the model parameter β is: $\hat{\beta} = (X'X)^{-1} X'y$ where X is an $(n \times p)$ model matrix and y is an $(n \times 1)$ vector of observed responses. All the standard techniques that are routinely used for model building in multiple linear regression are applied. This includes testing for significance, confidence intervals of the regression coefficients, and checking model adequacy. It is customary to use coded variables in RSM. The coded variable is computed in the following manner: $x_{ij}^c = x_{ij} - \bar{x}_j / x_{hi(j)} - \bar{x}_j$ where x_{ij} is the value in the natural units, $\bar{x}_j$ is the mean value for the j th variable, and $x_{hi(j)}$ is the maximum value in the natural units for the j th variable. This results in the values of x_{ij}^c ranging from -1 to $+1$. One reason for using coded variables is that the magnitude of each regression coefficient represents the change in the response variable for one unit change in the independent variable. Therefore, the impact of each independent variable can be evaluated in an equivalent manner. To read more about linear regression and model building, see Myers^[2] or Draper and Smith.^[3]

2^k FACTORIAL DESIGNS

The most commonly used experimental design when several factors are being studied is a factorial design. A more specific group of factorial designs is the 2^k factorial design, where each of the k factors has only two levels. The two levels, for each factor, represent a low ($-$) and a high ($+$) level and thus define the region of interest. An example of a 2^2 factorial design is shown in Table 1, with a graphical description in Fig. 2. A 2^k factorial design can be used when there is knowledge that no curvature is present in the experimental region. This will often be applicable when studying a narrow *region of interest*. A 2^k factorial design can naturally be extended to create a second-order response surface design which will be discussed later. A 2^k factorial design is very applicable in the case of *screening designs*, where a researcher has numerous factors to study and needs to eliminate those factors that do not have an effect on the response variable. Those factors, which are found to be important, would be studied further in a second-order response surface design.

FRACTIONAL FACTORIAL DESIGNS

If the number of factors in a 2^k factorial design is relatively large, then the size of the experiment may be impractical. For example, a 2^7 factorial design would consist of 128 experimental runs. One way to combat this problem is to perform only a specific fraction of the factorial experiment. These types of designs are appropriately called *fractional factorial designs*. Fractional factorial designs are very practical in the case of screening experiments. A key assumption when implementing a *fractional factorial*

Table 1 A 2^2 Factorial Design

Experimental run	X_1	X_2
1	$-$	$-$
2	$-$	$+$
3	$+$	$-$
4	$+$	$+$

Fig. 2 A 2^2 factorial design

design is that higher-order interactions are negligible. Let us consider a simple example where a researcher has three factors of interest and only four experimental runs can be performed. In addition, there is the belief that two-way interactions are not present. In this case, a one-half fraction of a 2^3 factorial design (i.e., 2^{3-1} design) would be a reasonable choice. Fig. 3 provides a graphical description of this design. The following algorithm can be used in order to determine which experimental runs are selected to create an appropriate one-half fraction of a 2^k factorial design:

- Select a 2^{k-1} full factorial design.
- Then the k th factor (or additional column) of the design is generated by multiplying the (+) and (−) of each of the $k - 1$ columns.

In most cases a users will not need to rely on the aforementioned algorithm, as many statistical software packages can generate fractional factorial designs.

Table 2 provides the one-half fraction of a 2^3 factorial design. Because only a fraction of the complete factorial design is performed, the ability to differentiate between some of the factor effects will be sacrificed. When a factorial design is fractionated, some of the factor effects have the same estimate. Two or more effects that have identical estimates are said to be *aliased* with each other. In the one-half fraction of a 2^k factorial design, each effect has one alias. By observing Table 3, it should be apparent that the column for X_1 is identical with X_2X_3 (also $X_2 = X_1X_3$ and $X_3 = X_1X_2$). Therefore one cannot differentiate between the effect of X_1 and X_2X_3 . In most practical fractional factorial designs, higher-order interactions are aliased with main effects or lower-order interactions. This is why the assumption of negligible high-order interactions is vital when implementing a fractional factorial design.

Fig. 3 One-half fraction of a 2^3 factorial design

3	+	+	+	+	+	+
4	+	−	−	−	−	+

Iskandarani et al.^[4] used a 2^{4-1} design with two center runs in order to optimize the capsule and tablet formulation for an experimental drug. A fractional factorial design was very appropriate in their situation, with the belief that higher-order interactions (e.g., three-way interactions) and several two-way interactions were expected to have little or no effect on the response variables.

There are some attractive flexible features of fractional factorial designs. First, they can be projected into a complete factorial design for any subset of $k - 1$ factors. Suppose a researcher used a one-half fraction of a 2^5 factorial design in order to screen out unimportant factors. If no more than four of the five variables are found to have a significant effect on the response variable, then a full factorial of the significant variables can be constructed. Thus, the main effects and each two-way interaction for each of the significant variables can be estimated. The utility of fractional factorial designs relies on the *sparsity-of-effects principle*, which states that a system is usually dominated by a few of the main effects and low-order interactions. If the number of variables under study becomes large, then it may be necessary to consider a smaller fraction of the 2^k design (e.g., one-quarter fraction of a 2^k design), which will result in more aliasing among effects. Myers, Montgomery, and Anderson-Cook^[1] Box and Draper,^[5] and Montgomery^[6] provide additional discussion on fractional factorial designs.

OTHER SCREENING DESIGNS (PLACKETT-BURMAN)

Another very popular class of screening designs is the Plackett-Burman design, which was developed by Plackett and Burman.^[7] These designs are two-level designs, in which the number of experimental runs is in multiples of four. Plackett-Burman designs fill the sample size void that exists with the fractional factorial designs. An example of a Plackett-Burman design with $N = 12$ and $k = 7$ is presented in Table 4. The alias structure (i.e., confounding of factors) for the Plackett-Burman is very complex; thus one must take great care when the estimation of interaction effects is of interest. Lin and Draper^[8] discuss projective properties of the Plackett-Burman design, which allows the experimenter to follow up an initial design with runs that allow an efficient separation of main effects and

Table 4 Plackett-Burman Design With $N = 12$ and $k = 7$

Experimental run	X_1	X_2	X_3	X_4	X_5	X_6	X_7

11	−	+	−	−	−	+	+
12	−	−	−	−	−	−	−

interaction effects. Sastry and Khan^[9] executed a Plackett-Burman design in order to evaluate the effect of formulation variables on drug release measurements. They were able to reduce the number of factors from seven to three, which significantly decreased the number of experimental runs required for the CCD. To read more on screening designs, see Myers, Montgomery, and Anderson-Cook,^[1] Box and Draper,^[5] or Montgomery.^[6]

CENTER RUNS IN RESPONSE SURFACE METHODOLOGY

A center run (or center point) is an experimental condition that is performed at the center of the design region $[(x_1, x_2, \dots, x_k) = (0, 0, \dots, 0)]$. Including (or augmenting) center runs to a 2^k factorial design has a very important role in RSM. The addition of center points provides the ability to determine if *curvature* (or quadratic effects) is present in the experimental region. This can formally be evaluated by a single-degree-of-freedom test. The mean square for *curvature* is the following: $n_f n_c (\bar{y}_f - \bar{y}_c)^2 / n_f + n_c$ where n_f and n_c represent the sample size for the factorial portion and center runs, respectively; and $\bar{y}_f$ and $\bar{y}_c$ represent the mean response for the factorial portion and center runs, respectively. If the mean response for the factorial design points is drastically different from the mean response for the center runs, then the mean square for *curvature* would be large and thus there would be evidence that curvature is present in the design region. Including center runs in a design will determine if curvature is present but cannot formally estimate and test the curvature effects for each factor. The test for curvature tests the following hypothesis:

$$H_0 : \sum_{j=1}^k \beta_{jj} = 0 \quad H_1 : \sum_{j=1}^k \beta_{jj} \neq 0$$

Sendrek et al.^[10] included center runs to a 2^4 factorial design in order to determine if curvature was present in their experimental region. By using the center runs, they were able to determine that a second-order design would

better approximate the response surface (a center composite design with six center runs was implemented). Their application involved the optimization of the turbidity and cloud point of a nonionic surfactant solution. Another advantage of implementing center runs in a 2^k factorial design is to get an economically appealing estimate of “pure error” that is independent of model selection. In other words, the experimental error is purely a function of replication, rather than potentially insignificant factors. When pure replication is not present in an experimental design, the estimate for experimental error is a function of insignificant factors.

STEEPEST ASCENT/DESCENT

A primary objective of RSM is to optimize a product or process. There are many instances when the researcher is not operating in the region of the optimum. After a screening experiment has been completed, a typical next step is to determine if one is close to the *region of the optimum*. The *method of steepest ascent* (or *descent*) can be used so that the experimenter can move along the path of maximum (or minimum) increase in the response variable. If one is trying to maximize the response, then the user will be looking for the steepest ascent, whereas if the user is trying to minimize the response, then the user will be looking for the steepest descent. Fig. 4 provides a contour plot, which demonstrates how the method of steepest ascent works. In this hypothetical example, the researcher would move along the path whereby Temperature is decreased and Speed is increased. The following are general steps for the method of steepest ascent:

1. Fit a first-order model (screening design).
2. Compute the path of steepest ascent (or descent), so one can expect the maximum increase (or decrease) in the response variable.

Fig. 4 Method of steepest ascent

3. Conduct experimental runs along the path and observe the response. At some point along the path, the improvement will decline and eventually disappear. The reason for this is because the first-order model, which was used to create the path, will no longer represent the true experimental system.
4. Select a base for a second experiment, where the maximum (or minimum) response is observed along the path. The second experiment could be either a factorial design or a response surface design. Testing for lack of fit (interaction terms) and using center runs for evaluating curvature are often useful at this stage.

The improvement found with steepest ascent will often not be as great at later iterations. In addition, one may not have the resources or time to perform numerous iterations of the method. However, after one has completed the method of steepest ascent, one has now developed a base for conducting a subsequent experiment (e.g., second-order response surface design) in order to optimize. Myers, Montgomery, and Anderson-Cook^[1] indicate that no more than two steepest ascent procedures are expected to be helpful.

The path of steepest ascent is a function of the regression coefficients in the first-order model. The magnitude of the regression coefficients determines the actual path, whereas the sign of the coefficients establishes the direction. The regression equation, which produced the contour in Fig. 4, was: $\hat{y} = 29.5 - 3.0 \times \text{Temperature} + 4.0 \times \text{Speed}$ where the design range for Temperature was 200–300°F and the design range for Speed was 300–500 rpm. Select one variable (e.g., Temperature) as the reference variable. Typically, one would move one coded unit along the path for the reference variable. Therefore one would move one coded unit in the negative direction of the variable Temperature. The ratio of the regression coefficients is used to calculate the points along the path for all other variables. In this example, the incremental steps for the Speed variable, in coded units, would be $(4/3) = 1.33$ in the positive direction. Table 5 provides the points on the path for both the coded and natural units. The method of steepest ascent has a very intuitive appeal in that one would expect an increase in the

Table 5 Points on the Path of Steepest Ascent

	Natural units		Coded units	
	Speed	Temperature	Speed	Temperature
Base	400	250	0	0
Delta	133	–50	1.33	–1
Base + delta	533	200	1.33	–1
Base + 2delta	666	150	2.66	–2

response variable by decreasing Temperature and increasing Speed, with Speed having a slightly greater impact.

EXPERIMENTAL DESIGNS FOR FITTING A SECOND-ORDER RESPONSE SURFACE

After a researcher has identified important variables via a screening experiment and has an understanding of the location of the region of the optimum (based on either steepest ascent/descent or scientific knowledge), it is time to consider implementing a second-order response surface design in order to be able to fit a second-order model and as a result better characterize the true response surface and find optimum experimental conditions.

One of the more popular designs for fitting a second-order response surface is the central composite design (CCD). These designs were introduced by Box and Wilson.^[11] The CCD consists of a 2^k factorial design, $2 \times k$ axial points, and center points. The CCD for three variables is displayed in Fig. 5. The flexibility of the CCD evolves around the selection of the axial points and the number of center points. The axial points can reside on the faces of the cuboidal region, which provides three levels per variable, or extend outside the faces of the cube, which provides five levels of each factor (as shown in Fig. 5). The choice of axial points is often dependent on the *region of interest*. For example, if the region of interest is defined as cuboidal, then it would be reasonable to place the axial points at the faces of the cube. Both Sastry and Khan^[9] (discussed earlier) and Lipps and Sakr^[12] used a CCD, with axial points located at the face of the cuboidal region. Lipps and Sakr used RSM in order to understand the effects of key process parameters in the top spray fluidized bed on measured granule and tablet properties.

Fig. 5 A CCD for three variables

If the *region of interest* can be extended outside the cuboidal region (e.g., spherical), then the axial points can be extended outside the faces of the cube. Axial points typically range from 1.0 to $\sqrt{k}$, where $\sqrt{k}$ would represent a spherical design. Ogawa et al.^[13] used a spherical CCD in order to study the scale-up problem in the manufacturing of granules. The location of the axial points impacts the design property of rotatability. A design is rotatable if the prediction variance is constant for all points that are a common distance from the center of the design region. A CCD is rotatable if the axial point equal $\sqrt[4]{F}$, where F is the number of factorial design points. Having a stable prediction variance throughout the design region is certainly a desirable feature, given that a researcher may typically not know where one will want to predict. Branchu et al.^[14] implemented a four-factor rotatable CCD, with axial points that were two coded units from the center of the design, in order to model and to optimize the thermal stability of a model protein. The number of center runs also plays a key role in achieving the stability of the prediction variance throughout the design region. Myers, Montgomery, and Anderson-Cook^[1] indicate that for a spherical design, three to five center runs should be used, whereas for a cuboidal design, one to two center runs should be applied.

The CCD is very appealing because it allows sequential experimentation. For example, assume that a researcher is studying k variables via a screening design (e.g., 2^k factorial design or 2^{k-1} fractional factorial design) and based on the analysis only r variables ($r < k$) are found to be significant. Then $2r$ axial points and center points could be augmented to the original screening design in order to develop a CCD for r variables. Wehrle et al.^[15] demonstrated the sequential ability of RSM in order to determine which process factors affected the characteristics of the final produced granules and tablets. They began with a 2^2 factorial design and then used center runs to determine whether curvature was present in their experimental region. After it was determined that significant curvature was present, the original design was augmented with axial points at the face of the cube, which resulted in a CCD. Another biopharmaceutical application, which demonstrated the sequential nature of RSM, was presented by Hutchings et al.^[16] They used a 2^2 factorial design with center runs to determine which variables affected the response and if a second-order design would be necessary to approximate the response surface. Based on the analysis of their initial design, it was determined that a second-order design would more appropriately approximate the response surface. Axial points at $\alpha = \sqrt{2}$ and additional center runs augmented the factorial design in order to form a spherical CCD. This application involved understanding how cure time and curing temperature affected a commercially available ethylcellulose latex coating dispersion.

Another popular class of designs for fitting a second-order response surface are Box-Behnken designs (BBD), which were introduced by Box and Behnken.^[17] These designs

consist of three levels. Table 6 provides the design matrix for a Box-Behnken design with three variables and three center runs. A unique characteristic of the BBD is that it is spherical. Fig. 6 displays the BBD in the case of three variables. By comparing the geometric shapes of the BBD and the CCD, it should become apparent how to select between the two types of designs. Because the BBD is spherical in nature, it does not predict well at the extremes (or corners) of the design region. Therefore, the BBD should be limited to cases when predicting at the corners of the cube is not important. It is recommended that three to five center runs be used for a Box-Behnken design.

COMPUTER-GENERATED DESIGNS

There are instances when the classical response surface designs discussed in the previous section cannot be implemented in practice. Some possible reasons are as follows:

1. The number of experimental runs for the classical response surface designs are impractical

2. The design region under study is constrained, therefore classical response surface designs are not feasible
3. There are numerous qualitative variables being studied (qualitative variables are those factors that are not continuous in nature, e.g., type of solvent)

Computer-generated designs are based on various design-optimality criteria. *D-optimality*, which creates designs that do a good job of estimating model parameters, is the most popular design-optimality criterion. Another important design-optimality criterion is *I-optimality* (or *IV*). This criterion is used when prediction is of utmost importance. The user will need to provide several inputs (e.g., the assumed statistical model, sample size, range of the design variables, set of candidate points, design region constraints, and optimality criterion) in order to create a computer-generated design. The specific inputs for the user will depend on the statistical computer package. Another opportunity for using computer-generated designs is to augment (or improve) an existing experimental design with additional experimental runs. Statistical software packages like JMP®, SAS®, or Design-Expert® can create computer-generated designs. See Myers, Montgomery, and Anderson-Cook^[1] for a detailed discussion and many examples of computer-generated designs.

STATISTICAL ANALYSIS OF A RESPONSE SURFACE

After a researcher has completed the experimental work, often the goal is to locate the optimum operating condition (e.g., maximum, minimum, or target response). However, even more important is to truly understand the nature of the estimated response surface. A graphical representation of the estimate response surface is a vital part in understanding the response surface. Fig. 7 shows a 3-D plot of an estimate response surface, where a maximum estimated response is located in the experimental region. The maximum response is called a *stationary point*, which is where the derivatives of estimated response with respect to the design variables are all zero. There are situations where the stationary point is neither a maximum nor a minimum. In this particular case, the stationary point is classified as a *saddle point*. Fig. 8 illustrates an estimated response surface, where a saddle point exists. Another graphical method used to interpret a response surface is a contour plot. Figs. 9 and 10 illustrate contour plots in the case of a maximum response and a saddle point, respectively. Most of the applications of RSM mentioned previously used 3-D plots and/or contour plots to better understand how the factors affect the response and to locate possible optimum experimental conditions.

It can be more difficult to make clear interpretations of how the various factors are affecting the response

Fig. 7 A 3-D plot of a response surface

Fig. 8 An estimated response surface of a saddle point

Fig. 9 A contour plot of a maximum response

Fig. 10 A contour plot of a saddle point

variable via the 3-D or contour plot when the number of independent variables becomes large. This is especially true if the interaction between independent variables is present.

Canonical analysis is routinely used to determine whether the stationary point is a maximum, a minimum, or a saddle point. Canonical analysis starts with a rotation of the response function to a new set of axes, which correspond to the principal axes of the actual contour system. Looking at Fig. 10, the contour system with the new set of axes is provided. The second-order response surface model, in matrix notation, is $\hat{y} = \hat{\beta}_0 + \mathbf{x}'\hat{\beta} + \mathbf{x}'\hat{B}\mathbf{x}$ where $\hat{\beta}_0$ represents the estimated intercept, $\hat{\beta}$ represents linear coefficients, and $\hat{B}$ represents second-order coefficients. The nature of the stationary point is determined by looking at the signs and the magnitude of the eigenvalues of $\hat{B}$. If all the eigenvalues of are positive, then the stationary point is a minimum response. Therefore a move in any direction from the stationary point will result in an increase in the estimated response. If all the eigenvalues of are negative, then the stationary point is a maximum response. In this case, a move in any direction from the stationary point will result in a decrease in the estimated response. However, if the eigenvalues differ in sign, the stationary point is a *saddle point* and the change in the estimated response from the stationary point will depend on the direction one moves from the center of the design region.

The magnitude of the eigenvalue determines how sensitive the estimated response is as one moves away from the center of the experimental region in a given direction. For example, assume that both eigenvalues, in a two-variable case, are negative. Assume that one eigenvalue representing v_1 (similar to the x_1 direction) has a much larger absolute value than the eigenvalue representing

v_2 (this scenario is illustrated in Fig. 9). In this example, as one moves along the v_1 (or x_1) axis, there is a greater change in the estimated response, than when moving along the v_2 axis. Sendrek et al.^[10] used canonical analysis to determine the nature of the stationary point.

Situations can occur where there is a region, rather than a point, where the estimated optimum response exists. This is often termed a *stationary ridge*. Observing a stationary ridge can be very useful to the researcher because it indicates flexibility in operating conditions. Fig. 11 illustrates a contour plot, in a two-variable case, where a stationary ridge exists. In this example, the optimum region is a line. A rising (or falling) ridge can be present when the optimum region is found to be outside the experimental region. In this case, the experimenter may consider further experimentation along the rising ridge. This would be similar to steepest ascent. Fig. 12 provides an example of a rising ridge.

Even after canonical analysis has been performed, there are situations in which a researcher needs additional help in determining the best operating conditions. For example, assume that the stationary point is outside the experimental design (e.g., rising ridge), or that the stationary point is a saddle point. In these cases, *ridge analysis*, which determines the optimum response at a given distance from the center of the design region, can aid the statistical analysis. For more on analyzing response surfaces, see Myers, Montgomery, and Anderson-Cook.^[1] and Box and Draper.^[5]

MIXTURE EXPERIMENTS

All the discussions up to this point have involved experiments where the levels chosen for any control variable are independent of the levels chosen for other control

Fig. 11 A stationary ridge

Fig. 12 A rising ridge

variables. However, experimental situations do exist where the response variable is assumed to depend only on the relative proportions of the components (or ingredients) and not on the amount. These types of situations are classified as *mixture experiments*. Drug formulation is one area within biopharmaceutical research in which mixture experiments are commonly used. Because the response variable is dependent on the proportion of the components, the following constraint is imposed: $\sum_{i=1}^k x_i = 1$.

Because of this constraint, the experimental region is defined as a simplex, which is a regularly sided figure with k vertices in $k - 1$ dimensions. Fig. 13 provides the simplex coordinate system for three components. Each of the vertices of the simplex represents *pure blends*, which

Fig. 13 A simplex coordinate system for three components

are mixtures that make up 100% of a single ingredient. The edges of the simplex, halfway between each of the vertices, represent *binary blends*, which are mixtures that represent equal amounts of two components. The location of the simplex, where the three lines intersect represent a *ternary blend*, is a mixture that represents an equal amount of all three components. Mixture experiments require different types of designs than those previously discussed. Because the mixture design region is a simplex, all design points must be at the vertices, on the edge, or in the interior of the simplex.

One of the most commonly used designs in the case of a mixture experiment is the *simplex lattice design*. A $\{k,m\}$ simplex lattice design for k components contains design points that are uniformly placed on the simplex. The actual design points are determined whereby the proportions assumed by each component take the $m + 1$ equally spaced values from 0 to 1: $x_i = 0, 1/m, 2/m, \dots, 1$.

For example, a $\{3,2\}$ simplex lattice design would consist of six design points (three pure blends and three binary blends). Another commonly used design in a mixture experiment is the *simplex centroid design*. In a k -component simplex centroid design, $2^k - 1$ distinct design points are used. These design points are the k permutations of primary blends, the $\binom{k}{2}$ permutations of binary blends, and so on, and the overall centroid $(1/k, 1/k, \dots, 1/k)$. Chu et al.^[18] and Shah et al.^[19] provide two examples of mixture experiments in biopharmaceutical applications. Chu et al.^[18] used a 10-point simplex centroid lattice augmented with three interior points to study the viscosity characteristics of a polymeric mucoadhesive formulation in multi-component solvent vehicles, whereas Shah et al.^[19] used a non-traditional simplex lattice to study the effects of varying quantitative compositions of the three key components (micronized drug, corn starch, and anhydrous lactose) on the compactibility and dissolution rates of tablets.

In many mixture experiments, there are constraints on the proportions of the components. In these cases standard mixture experiments may not be practical and thus computer-generated designs based on a given optimality criterion (e.g., D-optimality) would be a viable option. In addition, experimenters will encounter situations where both mixture and non-mixture variables are studied in one experiment. For example, an experimenter may want to study several mixture components and several process variables that could affect the blending properties of the ingredients. One must take extreme care with the statistical analysis of mixture experiments given that they are not performed identically as those with factorial experiments. Software packages like JMP® and Design Expert® can design and analyze mixture experiments. Cornell^[20] and Myers, Montgomery, and Anderson-Cook^[1] provide additional discussions of mixture experiments.

ROBUST PARAMETER DESIGNS

In the 1980s, Dr. Genichi Taguchi introduced a concept called robust parameter design (RPD), which increased the awareness of reducing variation in products and processes. RPD is a concept that stresses the proper choice of the *control factors* in order to reduce variation caused by a second set of factors called *noise variables*. These noise variables often contribute a large portion of the total variability. Some examples of noise factors are environmental conditions, raw materials, and operators. The primary objective of robust parameter design is to select the conditions of the control factors that are robust to changes in the noise variable. Therefore the conditions of the control factors that produce the best combination of bias error and variance error should be selected.

There are times in the development stage where the noise variables can be controlled in an experiment. This provides opportunities where both the control factors and noise variables can be combined into a single experiment. Taguchi uses a signal-to-noise ratio (SNR) performance criterion in order to determine the conditions of the control variable that are most robust to noise variables. Since the introduction of RPD by Taguchi numerous alternative modeling, analysis, and experimental design strategies using RSM have been proposed. Myers, Montgomery, and Anderson-Cook^[1] discuss, in great detail, how RSM can be applied to the robust parameter design problem.

CONCLUSION

RSM has been shown to be a very valuable tool in biopharmaceutical applications. The ability to effectively develop an optimum product or process has been demonstrated through many real-life examples. An important component of RSM involves statistical experimental design, which involves using efficient screening designs in order to eliminate unimportant variables from further experimentation. Another experimental design aspect involves using efficient second-order response surface designs in order to accurately estimate the response surface within the design region. The sequential nature of RSM provides great value and flexibility to the researcher. If a researcher is not in close proximity to the region of optimum experimental conditions, then steepest ascent (or descent) allows one to more efficiently locate the region of the optimum. A second sequential feature of RSM is the ability to augment existing screening designs in order to produce designs that allow one to estimate a second-order response surface. A second key component of RSM involves statistical analysis. This involves canonical analysis and ridge analysis, which are valuable tools to better understand the estimated response surface. They allow a researcher to better locate potential optimum experimental conditions. In addition, graphical tools like 3-D

plots and contour plots are also very useful tools to better understand how the response variable changes within the design region. Even though RSM has been used extensively in biopharmaceutical applications since the 1980s, there are certainly more opportunities to use RSM in biopharmaceutical research in the future.

Abstract

This entry presents several classes of response-adaptive designs, and discusses the advantages and disadvantages of these designs, and the analysis of clinical trials based on adaptive designs.

INTRODUCTION

Response-adaptive designs, or response-adaptive randomization procedures, are designs that change allocation away from 50/50 based on responses observed so far in the trial. The desired allocation proportion is usually motivated by an ethical consideration of assigning more patients to better treatments. This review presents several classes of response-adaptive designs, and discusses the advantages and disadvantages of these designs, and the analysis of clinical trials based on adaptive designs. We also discuss goals for the allocation proportion and the power of treatment comparison in the trial where response-adaptive design is used.

RESPONSE-ADAPTIVE DESIGNS

The two main goals of response-adaptive designs^[1] are: (1) to maximize the individual patient's personal experience in a trial under certain restrictions, and (2) to reduce the overall number of patients (sample size) of a randomized clinical trial. The early ideas of adaptive designs can be traced back to Thompson^[2] and Robbins.^[3] Since then, two main families of response-adaptive designs have been proposed: (1) target-based, which is based on an optimal allocation target, where a specific criterion is optimized based on a population model; and (2) design-driven, where designs are driven by intuition and are not optimal in a formal sense.^[1,4]

Urn Models

One large class of response-adaptive designs is based on urn models (design-driven). Consider the simplest situation where two independent treatments "A" and "B" with binary outcomes are compared in the course of a trial. Let p_A be the probability of a success on treatment A and let p_B be the success probability of treatment B, with $q_A = 1 - p_A$ and

$q_B = 1 - p_B$. In addition, let n be the total number of patients in a trial, let n_A be the number of patients assigned to treatment A, and let n_B be the number of patients assigned to B, so that $n_A + n_B = n$. It is assumed that the outcome can be observed relatively quickly. Following the ethical imperative, one wants to change the allocation in the course of a trial so that more patients receive the treatment performing better thus far in the trial.

Play-the-Winner Rule

One of the first response-adaptive designs, the play-the-winner rule, was introduced by Zelen.^[5] The first patient is equally likely to receive one of the two treatments. The subsequent patient is assigned to the same treatment following a successful outcome, and to the opposite treatment following a failure. On average, the proportion of patients (n_A/n) assigned to treatment A is $q_B/(q_A + q_B)$.^[1] Therefore this design assigned more patients to the better treatment.

Randomized Play-the-Winner Rule

Wei and Durham^[6] and Wei^[7] suggested the randomized play-the-winner rule, a response-adaptive design that randomizes patients. An urn contains one ball of each type corresponding to the two treatments. When a patient arrives, a ball is drawn from the urn and then replaced. The patient receives corresponding treatment. If the outcome is a success, one ball of that type is added to the urn; otherwise, one ball of the opposite type is added to the urn. This design has the same limiting allocation proportion as the play-the-winner rule.

Drop-the-Loser Rule

According to the drop-the-loser rule,^[8] the urn starts with one ball of each treatment type and one ball of the so-called immigration type. When a patient arrives to be

randomized to a treatment, a ball is taken from the urn. If it is an immigration ball, the ball is replaced and two additional balls (one of each treatment type) are added to the urn. If it is an actual treatment ball, a patient is assigned to corresponding treatment and response is observed. If response is a failure, the ball is not returned to the urn. If response is a success, the ball is returned to the urn; hence the urn composition remains unchanged. On average, $nq_B/(q_A + q_B)$ patients are assigned to treatment A.

For clinical trials with K treatment ($K \geq 2$), an important family of urn models is the generalized Friedman's urn^[9] (also called generalized Polya's urn in literature), which includes the play-the-winner rule and the randomized play-the-winner rule as special cases. The properties of generalized Friedman's urn have been studied extensively.^[9–13] Another family of urn models is based on birth-and-death urn with immigration,^[14] which includes the drop-the-loser rule as a special case. Some special cases of birth-and-death urn have been proposed and studied recently.^[15–17] Many other urn models^[18–20] have been suggested for response-adaptive designs. These urn models and their properties are reviewed in Rosenberger.^[21]

There are several advantages of designs based on urn models: (1) urn models are intuitive and easy to implement in clinical trials; (2) they shift the allocation probability to better treatments; and (3) the properties of urn models have been studied extensively. For comparing two treatments ($K = 2$), the play-the-winner rule is a deterministic allocation procedure; therefore there is a possibility of selection bias.^[1] The randomized play-the-winner rule is a randomized design. Simulation studies^[22,23] have shown that the power of the treatment comparison might get lost when an adaptive urn model is used for allocation. The drop-the-loser rule is found to preserve power better than other adaptive urn designs.^[4,24,25]

There are several drawbacks of adaptive design based on urn models: (1) it can only target a specific allocation proportion; this allocation is usually not optimal in a formal sense; and (2) it can only be applied to the clinical trials with binary or multinomial responses. Modifications are necessary to apply urn models to clinical trials with continuous responses or survival responses.

Optimal Allocations

Response-adaptive designs were introduced following the ethical goal to maximize an individual patient's personal experience in the trial. Another important goal is to maximize the power of treatment comparison. These two goals usually compete with each other. Optimal allocation proportions are usually determined through some multiple-objective optimality criteria.^[26–29] Jennison and Turnbull^[29] described a general procedure for determining optimal allocation.

Consider the situation when two binomials are compared and the measure of interest is $p_A - p_B$. Let $\hat{p}_A$ and $\hat{p}_B$ be the corresponding maximum likelihood estimators of

p_A and p_B . The allocation that minimizes the variance of $\hat{p}_A - \hat{p}_B$ is the *Neyman allocation* with:

$$\frac{n_A}{n} = \frac{\sqrt{p_A q_A}}{\sqrt{p_A q_A} + \sqrt{p_B q_B}} \quad (1)$$

Note that if, for example, both p_A and p_B are less than 0.5, Neyman allocation will assign more patients to the inferior treatment. Another goal, a compromise between the ethical goal and efficiency, is to minimize the expected number of failures for a fixed variance of $\hat{p}_A - \hat{p}_B$. The *optimal allocation*^[23] for this goal is:

$$\frac{n_A}{n} = \frac{\sqrt{p_A}}{\sqrt{p_A} + \sqrt{p_B}} \quad (2)$$

For treatments with continuous outcomes, Dunnett^[30] considered an allocation rule for a set of multiple comparisons of $K - 1$ treatments vs. a single control. Dunnett proposed the following unbalance rule with an allocation ratio 1:1:1:...:1:. This allocation proportion is optimal when the variances of all $K - 1$ treatments and control are the same. It is still unclear how to find optimal allocations for general K treatment clinical trials.

Target-Based Response-Adaptive Designs

Because optimal allocation usually depends on some unknown parameters, we cannot implement it in practice, unless we estimate the unknown parameters sequentially. In this section, we introduce two allocation procedures that use sequential estimation of unknown parameters. We consider the case of comparing two treatments with binary responses. We also suppose that the optimal allocation is the target proportion.

Sequential Maximum Likelihood Procedure

1) To start, allocate $n_0 \geq 2$ patients to both treatments A and B, and 2) assume that we have assigned j ($j \geq 2n_0$) patients in the trial and their responses have been observed. Let $\hat{p}_A$ and $\hat{p}_B$ be the maximum likelihood estimates based on the j responses. Then we allocate the $(j + 1)$ st patient to treatment A with probability:

$$\frac{\sqrt{\hat{p}_A}}{\sqrt{\hat{p}_A} + \sqrt{\hat{p}_B}} \quad (3)$$

This design has been studied by Melfi and Page.^[31] The limiting allocation of this design is the optimal allocation^[32], $\left(\sqrt{p_A}/(\sqrt{p_A} + \sqrt{p_B})\right)$ and its properties have also been studied in Hu and Zhang.^[33]

Doubly Adaptive Biased Coin Design

This procedure is a generalization of the sequential maximum likelihood procedure.^[31] At first, allocate $n_0 \geq 2$

patients to both treatments A and B. Suppose we have assigned j ($j \geq 2n_0$) patients to treatment and are about to assign patients $j + 1$. Let $p = \sqrt{p_A}/(\sqrt{p_A} + \sqrt{p_B})$ be the desired allocation and let $\hat{p}$ be the desired allocation, replaced by the current estimates $\hat{p}_A$ and $\hat{p}_B$. Let j_A/j and j_B/j be the current proportions of patients that have already been allocated to A and B, respectively. Then the probability of assigning patient $j + 1$ to treatment A is given by:

$$g(j_A/j, \hat{p}) \quad (4)$$

where g is an allocation function. This design was first proposed by Eisele.^[34] The properties of the design have been studied recently.^[33,35] The following family of functions g has been proposed:^[33]

$$g(x, y) = \frac{y(x/y)^\gamma}{y(x/y)^\gamma + (1-y)((1-y)/(1-x))^\gamma} \quad (5)$$

where $\gamma \geq 0$.

Here we use a simple example with $\gamma = 2$ to illustrate the allocation procedure. Suppose we have already assigned $j = 12$ patients, $j_A = 6$ to A and $j_B = 6$ to B. We have observed a success rate of $\hat{p}_A = 2/3$ on A and $\hat{p}_B = 1/3$ on B. If we are interested in optimal allocation, then we can compute:

$$\hat{p} = \frac{\sqrt{\hat{p}_A}}{\sqrt{\hat{p}_A} + \sqrt{\hat{p}_B}} = \frac{\sqrt{2/3}}{\sqrt{2/3} + \sqrt{1/3}} = 0.586 \quad (6)$$

Then the probability of assigning the 13th patient to treatment A is computed as:

$$g(0.5, 0.586) = \frac{0.586(0.586/0.5)^2}{0.586(0.586/0.5)^2 + 0.414(0.414/0.5)^2} = 0.739 \quad (7)$$

Both sequential maximum likelihood procedures and doubly adaptive biased coin designs can be extended to K treatments.^[33]

Treatment Effective Mapping

Another family of response-adaptive designs is called treatment effect mapping.^[36] Rosenberger^[36] examined treatment effect mappings for continuous outcomes by using nonparametric linear rank statistic. This idea has been applied to several statistical models.^[37–39]

IMPORTANT ISSUES IN ADAPTIVE DESIGN

Variability and Power of Using Adaptive Designs

When using response-adaptive designs in clinical trials, the number of patients assigned to each treatment is a random variable. Therefore the power (for most testing hypotheses

and alternatives) is also a random variable.^[40] The variability of allocation has a strong effect on the power. This has been demonstrated by some simulations studies.^[22,23] Recently, Hu and Rosenberger^[24] show that the average power of a randomization procedure is a decreasing function of the variability of the procedure. Furthermore, a lower bound of the asymptotic variability of the allocation proportions for general-purpose adaptive designs is derived.^[25] Based on these theoretical results, we can compare different response-adaptive designs.

The drop-the-loser rule has minimum variability (lower bound) in the class of all response-adaptive procedures targeting urn allocation $q_B/(q_A + q_B)$. The doubly adaptive biased coin design can directly target any given allocation (may depend on unknown parameters). The parameter γ determines the variability of the procedure. At the extreme, when $\gamma = 0$, we have the sequential maximum likelihood procedure, which has the highest variability. As γ tends to ∞ , we have a procedure that attains the lower bound of any randomization procedure targeting the same allocation. But this procedure ($\gamma = \infty$) is entirely deterministic (except when $j_A/j = \hat{p}$). As γ becomes smaller, we have more randomization, but also more variability.

Overall, the doubly adaptive biased coin procedure is the most favorable design:^[24,25,33] 1) it is flexible in terms of targeting any desired allocation; 2) it can be applied to different types of responses; and 3) one can tune the parameter γ to reflect the tradeoff between the degree of randomization and variability, and the tradeoff between power and expected treatment successes. In a recently study of binary response,^[4] it has been shown that the doubly adaptive biased coin design ($\gamma = 2$) is always as powerful or more powerful than complete randomization (50/50) with fewer treatment failures.

Sample Size of Adaptive Designs

It is usually difficult to determine the required sample size for response-adaptive designs. This is because the allocation probabilities keep changing during a clinical trial when using response-adaptive design. For a fixed sample size, the number of patients assigned to each treatment is a random variable.^[40] Therefore the power is also a random variable for a fixed sample size.

In the literature, sample sizes of response-adaptive designs are calculated by ignoring the randomness of the allocations.^[1,35] As shown in one example of Hu,^[40] to achieve a target power of 0.8, the sample size is 62 from the formula^[1] (where the randomness of the design is ignored). If the sample size 62 is used, then, with 20% chance, the real power is less than 0.76.

Hu^[40] studied the properties of the power function of randomized designs and derived an approximate distribution of the power function for comparing two treatments when sample size is fixed. Based on the approximate distribution, a formula of the required sample size is then

obtained. In the above example, the required sample size should be 72, instead of 62. It also has been shown^[40] that a well-selected response-adaptive design requires a much smaller sample size compared with the equal allocation in certain cases.

Applying Adaptive Designs and Analyzing Data from Adaptive Designs

The randomized play-the-winner rule was used in the highly controversial extracorporeal membrane oxygenation (ECMO) study.^[41] A total of 12 patients were assigned, with only one patient assigned to conventional therapy and 11 assigned to ECMO. The only failure observed was in conventional therapy arm. It is reasonable to ask about the validity of such a trial.^[42,43] What went wrong? The randomized play-the-winner rule has a high variability of the allocation proportion (especially for small sample size $n = 12$). That is why only one patient was randomized to conventional therapy arm.

Adaptive designs have been implemented in several clinical trials, including a trial of crystalloid preload in hypotension for cesarean patients,^[44] a trial of fluoxetine vs. placebo in depression patients,^[45] and a four-arm trial in depression.^[46] Adaptive designs have also been used extensively in adaptive learning algorithms, game theory, as well as dynamical systems.^[47,48] Applications of adaptive designs in many different disciplines can be found in Flournoy and Rosenberger.^[49] Some general issues of implementing response-adaptive designs are discussed in Chapter 12 of Rosenberger and Lachin.^[1]

Inference for response-adaptive design is complicated because the treatment assignments depend on the responses. Likelihood-based inference was studied for different response-adaptive designs.^[50–53] In these papers, it has been shown that the maximum likelihood estimators are consistent and asymptotic normal under certain regularity conditions. For a clinical trial (binary responses) using the randomized play-the-winner rule,^[13,54] exact confidence intervals of the parameters p_A and p_B were derived. Confidence intervals can also be constructed following response-adaptive designs for censored survival data and binary responses.^[55] Rosenberger and Hu^[56] studied bootstrap confidence intervals for response-adaptive designs of K treatments.

CONCLUSION

In the above discussion, we assume that individual patient outcome will be immediately available. For clinical trials with delayed responses, we can update the urn when the response becomes available.^[13] The properties of urn model (the generalized Friedman's urn) with delayed responses are studied in some papers.^[57,58] For doubly adaptive biased coin designs, the unknown parameters are

estimated sequentially and the delayed responses effect these estimators. The properties of doubly adaptive biased coin design with delayed responses are unknown, and this is a topic of future research. It is also unclear how delayed responses will affect the birth-and-death urn and the treatment effective mapping.

We have focused on reviewing response-adaptive designs. In the literature, the term *adaptive designs* has been also used for designs that balance treatment assignments. The biased coin design of Efron^[59] has been proposed to force a sequential experiment to be balanced. After that, adaptive biased coin designs^[60,61] and generalized adaptive biased coin designs^[62] were proposed. Details and comparisons of balancing properties can be found in Rosenberger and Lachin.^[1]

Covariate information is often available and usually very important in clinical trials. In the literature, researchers have focused on how to balance treatment allocation on known covariates.^[63–66] Very few response-adaptive designs^[37,38] attempt to incorporate covariate information. How to use covariate information in response-adaptive design is a critical and conceptually difficult problem. This remains a very important topic of future research.

We have presented here our view on the use of response-adaptive designs in clinical trials. We apologize for not covering some important topics in adaptive designs. We hope that the discussion will point the readers in the right direction for a more comprehensive discussion of the different topics introduced.

Risk Ratio Analysis

Kung-Jong Lui

Department of Mathematics and Statistics, San Diego State University, San Diego, California, U.S.A.

Abstract

The goal of this entry is to provide readers with an overview of characteristics and statistical analysis of the risk ratio analysis.

INTRODUCTION

As the risk ratio (RR), defined as the ratio of probabilities of developing a disease between the population with exposure and the population without exposure to a risk factor, was introduced,^[1] the RR has been the most important index to measure the strength of association between a risk factor and a disease in etiological studies.^[2–4] When the underlying disease under investigation is rare and chronic, directly estimating RR will require us to follow up a large cohort for a long time period. This can often cause the practical difficulty. For a rare disease, however, the RR can be approximated well by the odds ratio (OR).^[1,3,4] Furthermore, as the OR is invariant and estimatable under various study designs, we can estimate the RR indirectly by assessing its approximation—the OR from a retrospective case–control study.

For a randomized clinical trial (RCT), we may define the RR as the ratio of probabilities of having an adverse event between an experimental treatment and a placebo group. As the probability of having the adverse event in an RCT may not be small, the RR and OR are not necessarily approximately equal to each other. Thus, we cannot estimate the RR through the estimation of OR in an RCT as done in many epidemiological studies. The goal of this article is to provide readers with an overview of characteristics and statistical analysis of the RR. First, we note the relations between RR and other quantitative indices used in RCTs. We further note some asymptotic properties of commonly used estimators for the RR. We discuss estimation of the RR under stratified binomial sampling in large stratum size and sparse data, test of homogeneity of the RR across strata, and estimation of the rate ratio (which is relevant to the RR) under stratified Poisson sampling. Finally, we include a brief discussion on the estimation of the RR under other study designs, including the cluster randomization trial and simple compliance study.

DEFINITION AND CHARACTERISTICS OF RR

Let p_1 and p_0 denote the probability of suffering an adverse event in the experimental treatment and placebo group, respectively. The RR is simply defined as $\gamma = p_1/p_0$. The range for the RR is $0 < \gamma < \infty$. When $RR = 1$, the risks of having the adverse event for two comparison groups are equal. When $RR < 1$, the risk of having the adverse event in the experimental treatment is less than that in the placebo. Similarly, when $RR > 1$, the risk of having the adverse event in the experimental treatment is larger than that in the placebo. Note that the ratio p_1/p_0 is generally different from $(1-p_1)/(1-p_0)$, the ratio of probabilities of not having the adverse event. However, all the following statistical methods for the RR can be slightly modified to estimate the other ratio if the latter is our interest.

RELATIONS BETWEEN RR AND OTHER INDICES

Suppose that based on our subjective knowledge, we can assume that the experimental treatment tends to be beneficial, so that $RR (=p_1/p_0) \leq 1$. For example, consider the example of poliomyelitis vaccine trial.^[5,6] Here, p_1 and p_0 denote the probability of being a case with poliomyelitis in the vaccinated and placebo groups. As the vaccine is expected to protect a fraction δ of those who would have developed poliomyelitis if they had not been vaccinated, we may assume that $RR \leq 1$. The relative difference δ ,^[5,6] representing the protection effect owing to vaccinating those subjects who would otherwise have poliomyelitis if they were in the placebo group is, by definition, equal to $1 - RR (= (p_0 - p_1)/p_0)$. Thus, the relative difference^[4–6] may also be called the relative risk reduction, which is one of the most frequently used indices to measure the efficacy of a treatment in RCTs.

If the outcome (or response) of interest is rare, as noted previously, the RR can be approximated by the OR, $p_1(1-p_0)/[p_0(1-p_1)]$. Furthermore, because the OR can be estimated from the retrospective data and be expressed by parameters of the logistic regression or log-linear model, which can easily account for the confounding effects, the OR is likely to be the most useful index to measure the association between a risk factor and a disease in epidemiology. As the probability of outcome may often not be small in RCTs, however, the good property of the OR that can approximate the RR well may not hold. Because it is difficult for clinicians to comprehend the treatment effect in terms of the ratio of two odds, the OR is less frequently used in RCTs than other indices, such as the RR, relative difference, and risk difference.^[3]

The “number needed to treat” (NNT), defined as “the average number of patients needed to treat in order to prevent one patient with the adverse event in the placebo group,” has been recently proposed to quantify the treatment effect in RCTs and evidence-based medicine.^[7] Because this index can be easily understood by clinicians, the NNT has increasingly become popular to summarize the treatment effect.^[4,8–10] When $p_0 > p_1$, by definition, we can rewrite the NNT as $1/[(1-RR)p_0]$. This suggests that for a fixed baseline adverse event rate p_0 , the closer the RR to 0, the smaller is the NNT.

When one can assume that the time $T_i(>0)$ of an adverse event for a randomly selected patient in treatment $i(i=1,0)$ follows the negatively exponential distribution: $\lambda_i \exp(-\lambda_i t)$, we can easily see that the RR of probabilities for obtaining a patient with the adverse event between treatments $i=1$ and 0 in a given fixed follow-up time T^* is simply equal to $(1-\exp(-\lambda_1 T^*)) / (1-\exp(-\lambda_0 T^*))$. This ratio can be easily shown to approximately equal λ_1/λ_0 when both $\lambda_i T^*$ are small. In other words, the RR and the hazards ratio would be approximately equal if the follow-up time is relatively short to the mean length of time for the adverse event under investigation.

ESTIMATION AND ASYMPTOTIC PROPERTIES

Suppose that we randomly assign n_1 patients to receive the experimental treatment and n_0 patients to receive the placebo. Suppose further that we obtain X_i ($i=1,0$) number of patients with adverse events. The number X_i then follows the binomial distribution with parameters n_i and p_i . The likelihood of the observed data is given by

$$L(p_1, p_0 | x_1, x_0) = \binom{n_1}{x_1} p_1^{x_1} (1-p_1)^{n_1-x_1} \times \binom{n_0}{x_0} p_0^{x_0} (1-p_0)^{n_0-x_0}$$

On the basis of the above likelihood, the maximum likelihood estimator (MLE) for p_i is

$$\hat{p}_i = X_i/n_i$$

which is the sample proportion of patients with adverse events for treatment i . By the functional invariance property of the MLE,^[11] the MLE for the RR is simply

$$\hat{\gamma} = \hat{p}_1/\hat{p}_0$$

Note that because there is a positive probability that $\hat{p}_0 = 0$, the MLE $\hat{\gamma}$ does not have a finite expectation $E(\hat{\gamma})$. Note also that because the sampling distribution of $\hat{\gamma}$, a ratio of two sample proportions, can be skewed, we may wish to apply the logarithmic transformation to improve its normal approximation when deriving the interval estimator for the RR. This leads us to obtain an asymptotic $100(1-\alpha)\%$ confidence interval for the RR to be^[12]

$$\left[\hat{\gamma} \exp(-Z_{\alpha/2} (\widehat{\text{Var}}(\log(\hat{\gamma})))^{1/2}), \right. \\ \left. \hat{\gamma} \exp(Z_{\alpha/2} (\widehat{\text{Var}}(\log(\hat{\gamma})))^{1/2}) \right]$$

where Z_α is the upper $100(\alpha)\%$ th percentile of the standard normal distribution and $\widehat{\text{Var}}(\log(\hat{\gamma})) = (1-\hat{p}_1)/X_1 + (1-\hat{p}_0)/X_0$. Katz et al.^[12] compared the above interval estimator with other interval estimators. They noted that the interval estimator using the logarithmic transformation can perform well in a variety of situations. Other transformation to alleviate the skewness of the sampling distribution for $\hat{\gamma}$ can be found elsewhere.^[13] Note that if we should obtain either of X_i 's to be 0, the above interval estimator would not be applicable. Whenever this occurs, we can apply the commonly used ad hoc procedure of adding 0.50 to each cell for sparse data in calculation of $\widehat{\text{Var}}(\log(\hat{\gamma}))$. Using such an adjustment, we cannot, however, eliminate the bias. Lui proposed the use of inverse sampling,^[14] in which we continue sampling patients until we obtain a predetermined number x_i of patients with adverse events.^[4,15–17] Under this sampling, Lui derived the uniformly minimum variance unbiased estimator as well as several interval estimators for the RR.

STRATIFIED BINOMIAL SAMPLING

When patients are difficult to recruit, we may employ a multicenter design to facilitate the collection of data. Say, we have S centers participating in our study. For each center s ($s=1,2,\dots,S$), suppose that we randomly assign n_{is} patients to receive the experimental treatment ($i=1$) or the placebo ($i=0$), and obtain X_{is} number of patients with the adverse event of interest. Because patients from the center are likely to have similar characteristics and to be examined by the same laboratory, the baseline risks of patients

are likely to vary between centers. To account for this confounding effect, we may apply stratified analysis with strata formed by centers. Let p_{is} denote the corresponding probability of having an adverse event for patients receiving treatment i in center s . The number X_{is} then follows the binomial distribution with parameters n_{is} and p_{is} . The RR in stratum s between the two treatments is defined as $\gamma_s = p_{1s}/p_{0s}$. Note that the MLE of γ_s is $\hat{\gamma}_s = \hat{p}_{1s}/\hat{p}_{0s}$, where $\hat{p}_{is} = X_{is}/n_{is}$. In the following discussion, we assume that γ_s is constant across strata and denote this common value by γ_c . The likelihood is then given by

$$L(\gamma_c, p_0 | x_1, x_0) = \prod_{s=1}^S \binom{n_{1s}}{x_{1s}} (\gamma_s p_{0s})^{x_{1s}} (1 - \gamma_c p_{0s})^{n_{1s} - x_{1s}} \binom{n_{0s}}{x_{0s}} p_{0s}^{x_{0s}} (1 - p_{0s})^{n_{0s} - x_{0s}}$$

where $p_0 = (p_{01}, p_{02}, \dots, p_{0S})'$ and $x_i = (x_{i1}, x_{i2}, \dots, x_{iS})'$ for $i=1, 0$. The above likelihood depends on γ_c and S and other nuisance parameters p_{0s} , $s=1, 2, \dots, S$. To obtain the MLE $\hat{\gamma}_c$ requires us to employ an iterative numerical procedure^[18] to find the value γ_c which maximizes the above likelihood. Greenland and Robins^[19] note that the MLE $\hat{\gamma}_c$ can be biased in the sparse data, in which the number of patients within strata is small, but the number of strata is moderate or large.

Estimation in Large Stratum Size

First, we consider the situation in which the stratum size is large. Because it is asymptotically efficient and simple for use, the most commonly used point estimator for γ_c under stratified sampling is the weighted least-squares (WLS) point estimator.^[3,4,20] Because the asymptotic variance $\widehat{Var}(\hat{\gamma}_s)$ is proportional to $\widehat{Var}(\log(\hat{\gamma}_s))$, when γ_s is constant, to estimate γ_c , we may apply the WLS point estimator $\hat{\gamma}_{WLS} = \sum_s \hat{W}_s \hat{\gamma}_s / \sum_s \hat{W}_s$, where $\hat{W}_s = \widehat{Var}(\log(\hat{\gamma}_s))^{-1}$ and $\widehat{Var}(\log(\hat{\gamma}_s)) = [(1 - \hat{p}_{1s}) / (n_{1s} p_{1s}) + (1 - \hat{p}_{0s}) / (n_{0s} p_{0s})]$. When deriving the interval estimator for γ_c , we commonly employ the logarithmic transformation and obtain an asymptotic $100(1 - \alpha)\%$ confidence interval for γ_c to be

$$\left[\exp \left\{ \frac{\sum_s \hat{W}_s \log(\hat{\gamma}_s)}{\sum_s \hat{W}_s} - Z_{\alpha/2} / \sqrt{\sum_s \hat{W}_s} \right\}, \exp \left\{ \frac{\sum_s \hat{W}_s \log(\hat{\gamma}_s)}{\sum_s \hat{W}_s} + Z_{\alpha/2} / \sqrt{\sum_s \hat{W}_s} \right\} \right]$$

Note that if either $\hat{p}_{1s}$ or $\hat{p}_{0s}$ equals 0 in stratum s , the WLS estimators will be undefined. If this occurs, we may add 0.50 to each cell when calculating $\hat{\gamma}_{WLS}$ or the above interval estimator.

Estimation in Sparse Data

When the data are sparse (i.e., all n_{is} are small), however, using the WLS interval estimator even with the above ad hoc adjustment procedure of adding 0.50 to each cell can be misleading (i.e., the point estimator $\hat{\gamma}_{WLS}$ is seriously biased and the coverage probability of the interval estimator based on $\hat{\gamma}_{WLS}$ can be much less than the desired confidence level). These lead us to consider the Mantel-Haenszel (MH) type estimator:^[21–23]

$$\hat{\gamma}_{MH} = \left(\sum_{s=1}^S \bar{\omega}_s \hat{p}_{1s} \right) / \left(\sum_{s=1}^S \bar{\omega}_s \hat{p}_{2s} \right)$$

where $\bar{\omega}_s = n_{1s} n_{0s} / n_{.s} n_{.s} = n_{1s} + n_{0s}$. Note that the MH estimator $\hat{\gamma}_{MH}$ is defined as long as there is at least one $\hat{p}_{2s} > 0$. Greenland and Robins^[19] derived an estimated asymptotic variance of $\hat{\gamma}_{MH}$ for sparse data:

$$\widehat{Var}(\log(\hat{\gamma}_{MH})) = \left\{ \sum_s [n_{1s} n_{0s} (X_{1s} + X_{0s}) - n_{.s} X_{1s} X_{0s}] / n_{.s}^2 \right\} / \left\{ \left(\sum_s \bar{\omega}_s \hat{p}_{1s} \right) \times \left(\sum_s \bar{\omega}_s \hat{p}_{0s} \right) \right\}$$

Thus, we obtain an asymptotic $100(1 - \alpha)\%$ confidence interval for γ_c to be

$$\left[\hat{\gamma}_{MH} \exp \left\{ -Z_{\alpha/2} (\widehat{Var}(\log(\hat{\gamma}_{MH})))^{1/2} \right\}, \hat{\gamma}_{MH} \exp \left\{ Z_{\alpha/2} (\widehat{Var}(\log(\hat{\gamma}_{MH})))^{1/2} \right\} \right]$$

This interval is valid for use even for the case of one-to-one matching. For further information, we refer readers to publications^[24–26] that evaluate and compare various interval estimators of the RR in sparse data.

Test of Homogeneity of RR

Before we obtain a summary estimator for the underlying common γ_c , it is important for us to examine the assumption that $H_0: \gamma_1 = \gamma_2 = \dots = \gamma_s = \gamma_c$ to avoid overlooking the possible interaction effect between treatment and stratum effects on the outcome. When the stratum size is extremely large, we may apply the WLS test statistic.^[3,4]

$$T_{WLS} = \sum_s \hat{W}_s \left[\log(\hat{\gamma}_s) - \frac{\sum_s \hat{W}_s \log(\hat{\gamma}_s)}{\sum_s \hat{W}_s} \right]^2$$

and reject H_0 at α -level if $T_{WLS} > \chi_{\alpha, S-1}^2$, where $\chi_{\alpha, S-1}^2$ is the upper $100(\alpha)\%$ th percentile of the χ^2 -distribution with $S-1$ degrees of freedom. Lui and Kelly^[27] note that this WLS test procedure can be quite conservative if the stratum size is not large. To improve this test procedure, Lui and Kelly

develop several other alternative test procedures. For its simplicity, we present only the following simple test procedure, which is generally preferable to the above WLS test procedure.^[4,27] We define the test statistic

$$T_{WLS}^* = (T_{WLS} - (S-1)) / \sqrt{2(S-1)}$$

Note that when γ_s varies between strata, we expect T_{WLS} to be large. Thus, we reject H_0 at α -level if $T_{WLS}^* > Z_{\alpha}$. When the data are sparse, none of the test procedures considered by Lui and Kelly can perform well. Recently, Lui^[28] concentrates attention on sparse data and develop a simple test procedure based on the beta-binomial model by using the bootstrapping method^[29] for testing the homogeneity of relative difference. Lui demonstrates that his procedure can perform well even when the stratum size is as small as two patients per treatment in a variety of situations. Because the relative difference is equal to $1 - RR$ (when $RR \leq 1$), we may modify Lui's test procedure to test the homogeneity of the RR focused here. We refer readers to this article for details.

ESTIMATION UNDER STRATIFIED POISSON SAMPLING

When the treatment effect takes years to develop, many patients may drop out during the lengthy follow-up period. Thus, it is important to account for various person-time units at risk between the comparison groups. The Poisson model, which can easily incorporate this information into data analysis, is often employed.^[30,31]

Suppose that in an RCT, we want to assess the ratio of the adverse event rates between the experimental treatment ($i=1$) and the placebo ($i=0$) and suppose that we obtain X_{is} number of patients with the adverse event in T_{is} person-time units of follow-up from group i ($i=1,0$) in stratum s ($s=1,2,\dots,S$), we assume that X_{is} independently follows a Poisson distribution: $(\lambda_{is} T_{is})^{X_{is}} \exp(-\lambda_{is} T_{is}) / X_{is}!$, where λ_{is} is the adverse event rates. The rate ratio (which is, explicitly speaking, different from the RR discussed above) is defined as $\gamma_s^* = \lambda_{1s} / \lambda_{0s}$. The MLE of γ_s^* is simply given by $\hat{\gamma}_s^* = \hat{\lambda}_{1s} / \hat{\lambda}_{0s}$, where $\hat{\lambda}_{is} = X_{is} / T_{is}$. In the following discussion, we assume that γ_s^* is constant across strata and denote this common value by γ_c^* . If the expected number of cases per treatment in each stratum is large, we may use the WLS point estimator to estimate the underlying common rate ratio γ_c^*

$$\hat{\gamma}_{WLS}^* = \sum_s \hat{W}_s^* \hat{\gamma}_s^* / \sum_s \hat{W}_s^*$$

where $\hat{W}_s^* = \widehat{\text{Var}}(\log(\hat{\gamma}_s^*))^{-1}$ and $\widehat{\text{Var}}(\log(\hat{\gamma}_s^*)) = 1/X_{1s} + 1/X_{0s}$. Furthermore, when applying the WLS interval estimator with the logarithmic transformation, we obtain an asymptotic $100(1-\alpha)\%$ confidence interval for γ_c^* to be

$$\left[\exp \left\{ \sum_s \hat{W}_s^* \log(\hat{\gamma}_s^*) / \sum_s \hat{W}_s^* - Z_{\alpha/2} / \sqrt{\sum_s \hat{W}_s^*} \right\}, \right. \\ \left. \exp \left\{ \sum_s \hat{W}_s^* \log(\hat{\gamma}_s^*) / \sum_s \hat{W}_s^* - Z_{\alpha/2} / \sqrt{\sum_s \hat{W}_s^*} \right\} \right]$$

When the expected number of cases per treatment in each stratum is small, we may also consider the MH estimator^[18] for the rate ratio

$$\hat{\gamma}_{MH}^* = \sum_s X_{1s} T_{0s} / T_{1s} \bigg/ \sum_s X_{0s} T_{1s} / T_{0s}$$

where $T_{.s} = T_{1s} + T_{0s}$. The estimated asymptotic conditional variance of $\hat{\gamma}_{MH}^*$ is^[30]

$$\widehat{\text{Var}}(\hat{\gamma}_{MH}^*) = \hat{\gamma}_{MH}^* \left(\sum_s T_{1s} T_{0s} x_{.s} / T_{.s}^2 \right) / \left[\sum_s T_{1s} T_{0s} x_{.s} / (T_{.s} (\hat{\gamma}_{MH}^* T_{1s} + T_{0s})) \right]^2$$

These lead to obtain an asymptotic $100(1-\alpha)\%$ confidence interval for γ_c^* to be

$$\left[\hat{\gamma}_{MH}^* \exp \left\{ -Z_{\alpha/2} (\widehat{\text{Var}}(\log(\hat{\gamma}_{MH}^*)))^{1/2} \right\}, \right. \\ \left. \hat{\gamma}_{MH}^* \exp \left\{ Z_{\alpha/2} (\widehat{\text{Var}}(\log(\hat{\gamma}_{MH}^*)))^{1/2} \right\} \right]$$

where $\widehat{\text{Var}}(\log(\hat{\gamma}_s^*)) = \widehat{\text{Var}}(\hat{\gamma}_s^*) / (\hat{\gamma}_s^*)^2$. Recently, Lui^[31] has considered and compared eight interval estimators for the rate ratio, including the above two interval estimators presented here. Lui has noted that the interval estimator using Wald's statistic with the logarithmic transformation and the two other test-based confidence intervals based on the conditional distribution tend to be more efficient than the above interval estimator based on the MH estimator. However, using the former requires the use of iterative numerical procedures, while using the latter is much easy to calculate.

To test the homogeneity of the rate ratio between strata, we may employ the asymptotic likelihood ratio test proposed by Rothman and Boice^[18]

$$T_{LR} = 2 \left\{ \sum_s [x_{1s} \log(\hat{\gamma}_s) - x_{.s} \log(T_{1s} \hat{\gamma}_s + T_{0s})] \right. \\ \left. - \sum_s [x_{1s} \log(\hat{\gamma}_c) - x_{.s} \log(T_{1s} \hat{\gamma}_c + T_{0s})] \right\}$$

where $\hat{\gamma}_c$ is the conditional MLE and is the root γ_c satisfying the equation

$$x_{1.} = \sum_s x_{.s} T_{1s} \gamma_c / (T_{1s} \gamma_c + T_{0s})$$

where $x_{1.} = \sum_s x_{1s}$ and $x_{.s} = X_{1s} + X_{0s}$. If we obtain $T_{LR} > \chi_{\alpha, S-1}^2$, we will reject the null hypothesis $H_0: \gamma_1 = \gamma_2 = \dots = \gamma_S$ at α -level. Lui^[31] has given a sufficient and necessary condition for the existence of a unique finite conditional MLE $\hat{\gamma}_c$ and provided a numerical procedure to find $\hat{\gamma}_c$.

OTHER STUDY DESIGNS

When comparing an experimental treatment with a standard treatment (or a placebo), some patients assigned to the experimental treatment may decline and switch to the standard treatment. For example, consider the study of using vitamin A supplementation to reduce mortality in preschool children.^[32] Nearly 20% of children failed to take the vitamin A supplement. To assess the effect of vitamin A, we may need to account for this compliance information when estimating the RR of mortality among children who would be willing to take vitamin A.^[33] Readers may find a systematic discussion on interval estimation of the RR for this simple compliance study design (Lui, K.-J. Notes on interval estimation of risk ratio in the simple compliance randomized trial. Department of Mathematics and Statistics, San Diego, CA, unpublished manuscript.). Because the data structure for this type of simple compliance study is essentially parallel to the single consent-randomized design,^[34,35] the interval estimator of the RR for the former is applicable to the latter as well.

For administrative convenience, cluster randomization trials, in which the unit of randomization is a class, a household or a spouse pair, are widely used for evaluating an intervention of the prevention of a disease.^[36–39] As the responses on patients within clusters are likely correlated, it is important to incorporate this intraclass correlation into estimation to avoid overestimating the precision. Owing to the space limitations, we refer readers to publications^[4,37,39] in which some examples and discussions on interval estimation of the RR for cluster randomization trials can be found.

CONCLUSIONS

Because the RR, representing the times of the risk that a randomly selected patient has an adverse event in the experimental treatment relative to that in a placebo, can be easily understood, the RR (or equivalently, the relative risk reduction $1 - \text{RR}$) is one of the most useful indices to summarize the treatment effect in RCTs. By contrast, the OR, although which is frequently used to locate the potential cause of a disease in epidemiology, is more difficult to interpret itself when it cannot approximate the RR well. The discussion on the characteristics of the RR, the relations between the RR and other indices, and estimation of the RR under various study designs presented here should have use for biostatisticians and clinicians when they wish to employ the RR to present their clinical findings.

Abstract

The receiver operating characteristic (ROC) curve has become a useful tool to distinguish differences in diagnostic performance. This entry is focused on breaking down the details of the ROC curve and provides statistical designs, methods, and analysis.

INTRODUCTION

In the recent development of diagnostic imaging, the receiver operating characteristic (ROC) curve has become a useful tool to distinguish differences in diagnostic performance. Use of this method enhances the traditional measures, and is now well established. The conventional approach of most diagnostic tests is to provide a dichotomous outcome (positive/negative of test result and presence/absence of disease status). The accuracy of test performance is then evaluated by “sensitivity” and “specificity.” The sensitivity is the probability that a test result is positive given the presence of disease. On the other hand, the specificity is the probability that a test result is negative given the absence of disease. However, very often a single pair of sensitivity and specificity measurements may provide a possibly misleading and even hazardous oversimplification of accuracy.^[1] This is why the ROC curve needs to be established.

For many diagnostic tests, the test data do not necessarily fall into one of two obviously defined categories. It is required that some confidence threshold be established in the mind of the decision maker, e.g., how strong the suspicion for the test result to be called as positive if the test suggests the possibility of disease. Therefore, the decision maker chooses between a positive and negative test result by using his/her confidence with an arbitrary confidence threshold, such as definitely negative, probably negative, questionable, probably positive, and definitely positive. Thereafter, an ROC curve is determined by a plot of sensitivity (usually on the vertical axis) vs. 1-specificity, which depicts sensitivity and specificity levels over the entire range of decision thresholds. Consequently, an ROC curve provides more information than just a single sensitivity and specificity pair to describe the accuracy of a set of test results.

ROC methodology was originally developed for electronic signal detection and evaluations of radar signals in

the early 1950s. In the mid-1960s, ROC curves were used in experimental psychology and other nonmedical fields. In the late 1960s, the radiologist Leo Lusted suggested using ROC analysis in medical decision making. The first ROC curve applied in studies of medical imaging devices was in 1969.^[2]

REGULATORY REQUIREMENTS

In 1998, the Food and Drug Administration (FDA) in the United States proposed a draft guidance to clarify the evaluation and approval of in vivo radiopharmaceuticals used in the diagnosis or monitoring of diseases. The purpose of the regulations is to respond to the requirements of the Food and Drug Administration Modernization Act of 1997 (FDAMA). In the regulations, certain types of indications for which the FDA may approve diagnostic radiopharmaceuticals are described. In addition, the criteria that the agency would use to evaluate the safety and effectiveness of a diagnostic radiopharmaceutical under the Federal Food, Drug, and Cosmetic Act (the act) and the Public Health Act (the PHS act) are included.

The FDA draft guidance^[3] requires special considerations in clinical design and analysis for medical imaging drugs and biologics. The ROC curve is recommended as one of several methods for the assessment in diagnostic validity, and ROC analysis can be used to evaluate diagnostic accuracy.

In 2004 a revised version of the guidance was issued, with no additional suggestions for the use of ROC analysis. In 2009, the European Medicines Agency (EMA) issued a revised version of a guidance originally adopted in 2001.^[4,5] The guidance states that although ROC curves are mainly considered to be a means for selecting appropriate cutoff points to be used prospectively in confirmatory trials, the area under the curve may also be used as a measure of diagnostic performance.

STATISTICAL DESIGN/METHOD/ANALYSIS

Construction of a Receiver Operating Characteristic Curve

As mentioned in the introduction, an ROC curve is a plot of sensitivity (or true positive fraction, TPF) vs. 1-specificity (false positive fraction, FPF). These two measures together quantify the accuracy of a test or method in classifying an experimental unit into one of two categories, usually referred to as “positive” or “negative.” The construction of the ROC curve depends on a continuous or an ordinal scale representing a series of “cut-off points” based on the confidence threshold from the less to the most confidence in a positive decision. An example of the cut-off points in an ROC curve is shown in Table 1.

Using Table 1, different pairs of the TPF and FPF derived from five cut-off confidence thresholds may be generated. The ROC curve is then constructed by plotting these pairs of (FPF, TPF). An example of the ROC curve is illustrated in Fig. 1, which is contained in the unique square with scale ranging from 0 to 1 in both *x*- and *y*-axis. The better performance of a diagnostic test is indicated by the ROC curve passes near the upper left corner at (0,1), where the FPF is 0 (100% of specificity) and the TPF is 1 (100% of sensitivity). If the test performance were almost random, then the ROC curve would lie near the 45-degree diagonal line.

Given this finite set of points that determine the ROC curve, generation of the remaining points and other measures associated with the curve may be done by either assuming some underlying distribution or not doing so.

Table 1	An Example of Cut-Off Points Scale in ROC Curve				
Scale	– 2	– 1	0	1	2
Confidence threshold	Definitely negative	Probably negative	Not sure	Probably positive	Definitely positive

Fig. 1 Construction of an ROC curve

The most common distribution assumed for ROC curves is binormal distribution,^[2] which is described in the next section. For nonparametric approach, the methods are illustrated in the last section under biopharmaceutical applications of ROC curve.

Fitting a Binormal Receiver Operating Characteristic Curve

This family of curves results from assuming that the underlying data for both the positive and negative cases follow normal distributions, possibly with different parameters. This implies that the points on the ROC curves will fall on straight lines when plotted on axis transformed to normal scales. Each binormal ROC curve can be determined by two parameters. One possible way to parameterize these curves is by the slope and *y*-intercept of the line in “binormal space.”^[2] Given that μ_1 and σ_1 are the mean and standard deviation of the normal distribution of the negative or nondiseased units, and that μ_2 and σ_2 are the mean and standard deviation of the normal distribution of the positive or diseased units, then the “slope” parameter is $b = \sigma_1/\sigma_2$ and the intercept parameter is $a = (\mu_2 - \mu_1)/\sigma_2$.^[6]

The process of fitting the curve involves estimating the aforementioned parameters, *a* and *b*. Least squares methods are not appropriate for the estimation of *a* and *b*, but maximum likelihood techniques may be used because the assumptions that underlie the least squares methods are not valid for ROC data. The maximum likelihood estimation is used to produce parameter estimates as well as variability estimates.^[7]

Summary Measures for Receiver Operating Characteristic Curves

Despite the fact that no single number can define or characterize an ROC curve, questions may need to be answered that involve comparisons of two or more curves. These situations make desirable the calculation of meaningful summary statistics that best characterize the entire ROC curve. Several have been proposed, the most common of which are discussed subsequently.

Area Under the Receiver Operating Characteristic Curve

Although the ROC curve provides the diagnostic accuracy over the full range of decision thresholds, it would be helpful if the diagnostic performance could be quantified by a single number. One such measurement that can be derived from the ROC curve is the area under the curve (AUC). The AUC may be calculated by summing the areas of the individual trapezoids that comprise the region under the curve. The area under the ROC curve is a type of average of the ordinate values on the curve, and it therefore represents an average probability of correctly classifying a

case chosen at random. Also, the meaning of AUC has been proved to be the probability that a random pair of (FPF, TPF) individuals would be identified correctly by the diagnostic test.^[8] According to Hanley and McNeil in 1982,^[9] “The area under the ROC curve measures the probability, denoted by θ , that in randomly paired normal and abnormal images, the perceived abnormality of the two images will allow them to be correctly identified.” In other words, the greater the FPF and TPF values, the greater the AUC, which presents the better predictive ability. According to Hosmer and Lemeshow,^[10] the general rule of predictive ability for AUC is:

AUC	Predictive ability
0.5	No predictive ability
0.7 to <0.8	Acceptable predictive ability
0.8 to <0.9	Excellent predictive ability
≥0.9	Outstanding predictive ability

Based on the mathematical derivations, the area under the ROC curve is a function of the Wilcoxon rank-sum statistic.^[9] Based on this fact, therefore, the comparison of ROC curves may be calculated. The area under the binormal ROC curve is a simple function of the parameter estimates a and b mentioned earlier. In other words, the area under the binormal ROC curve equals the area under the standard normal curve from $-\infty$ to $a/\sqrt{1+b^2}$.^[6]

Partial Area Under the Receiver Operating Characteristic Curve

The greatest disadvantage of the full area under the ROC curve is the equal weight given to all false positive error rates. Practically, there are points and/or regions of the ROC curve that are of more interest than others when evaluating the performance of one or more diagnostic procedures. For example, if tests with very low sensitivity or specificity are considered undesirable, then the regions at or near the extremes of the curve are of no practical interest. Given minimum acceptable values for sensitivity or specificity (or some other criteria by which to partition the curve), a sector of the ROC curve is defined, and the area of the region under this sector may be used as a measure of the accuracy. For a binormal ROC curve, this area can be expressed as a simple closed form integral involving the standard normal probability function.^[6] This may then be “standardized” to a measure more like an average accuracy by dividing the area by the absolute difference of the horizontal (false positive rate) coordinates.

Single Points on the Receiver Operating Characteristic Curve

An extreme variation on using a region of the ROC curve would be to use just some single predefined point as the

basis for evaluation. Typically, points are chosen on their respective ROC curve where either the sensitivity and specificity are equal or some predetermined point where either sensitivity or specificity is a given value, such as 90%. For example, some medical applications may require the diagnostic with high specificity, Linnet^[11] suggested comparing two sensitivities under a single fixed level of specificity, p_0 .

Logistic Regression and Receiver Operating Characteristic Curve

The probability of correctly predicting the event in ROC analysis, measured by the AUC, is similar to the predicted probability in the logistic regression model. For a single test with no covariate, the classification table based on the logistic regression is the same as the conventional diagnostic tests, which provide a dichotomous outcome. By changing the cut-off points in the classification table of the logistic regression model, the ROC curve can be constructed accordingly. The comparisons of different curves are then analyzed by the methods described before, such as AUC.

Biopharmaceutical Applications of Receiver Operating Characteristic Curve

Choosing a Cut-Off Point for Positive Result for Confirmatory Trials

If a given diagnostic test yields a continuous or near-continuous result that is used to classify a patient into one of two categories, the ROC curve is very useful in identifying the optimal value to use as a cut-off point for the classification. For example, if a biochemical marker is a candidate for use in diagnosing a medical condition, samples may be taken in subjects with and without the condition. The ROC curve produced by choosing cut-off points across the full range of values for the marker provides a full picture of test performance, and should be able to provide guidance as to the best choice of standard for classifying a subject as a positive or negative case.

Similarly, if a confidence scale is associated with the classification of patients into “diseased” or “nondiseased” categories, the trade-off between sensitivity and specificity by using various confidence levels to conclude disease state can be effectively compared using the ROC curve.

Characterizing Accuracy with Summary Measures

One desirable feature of the ROC curves is that they provide a measure of accuracy, which incorporates both sensitivity and specificity. Clearly they have to be viewed as a pair when they are used to characterize the accuracy of a diagnostic method. Merely providing one of these two rates as evidence is generally not acceptable. Each of the

previously mentioned summary measures for ROC curves is a single number that incorporates both sensitivity and specificity. This collapsing of a two-dimensional situation to a single dimension serves an important statistical purpose, as it makes possible the specification of simple decision rules based on a single parameter. For example, if a given method is known to have a sensitivity of 90% and a specificity of 60%, and an alternate method has a sensitivity of 85% and specificity 80%, there is not a clear ordering of the performance of the two methods. Because ROC curve indices will be single numbers, a natural comparison by order is evident.

It is interesting to note the relationship between one of the most commonly used ROC summary measures, the entire area under the ROC curve, and the sometimes criticized measure of overall accuracy. If an ROC analysis is performed using a single sensitivity and specificity, the resulting empirical curve would be a quadrilateral whose area is equal to the average of the sensitivity and specificity. This can be seen by considering the three points in the unit square that would result: (0,0), (FPF, TPF), and (1,1). The areas of the resulting triangle and trapezoid are $1/2(\text{FPF})(\text{TPF})$ and $1/2(\text{TPF} + 1)(1 - \text{FPF})$, respectively. By adding both areas would result $1/2(\text{TPF} + 1 - \text{FPF})$, which is the average of sensitivity and specificity. Given equal numbers of positive and negative cases, this quantity is exactly the same as the overall accuracy.

Combining the Separate Measures of Accuracy and Diagnostic Confidence

In some studies, both the correctness of diagnosis and a separate measurement of confidence for the diagnosis are available. ROC analysis can be used to combine the accuracy and the diagnostic confidence, provided that the diagnosis and standard of reference are dichotomies (positive/negative or diseased/nondiseased). For example, if a diagnostic method yields results of + and – for a target disease and a rating physician provides a response of 0 = uncertain, 1 = fairly confident, 2 = very confident with his/her diagnosis, the pair of responses may be transformed into the following scale:

Combining assessment	Very confident case of –	Fairly confident case of –	Uncertain	Fairly confident case of +	Very confident case of +
Scale	– 2	– 1	0	1	2

With this transformation, the area under the ROC curve could be used to analyze accuracy and confidence simultaneously. Higher areas result from having high confidence when diagnoses are correct, and lower confidence when diagnoses are incorrect. These characteristics provide a reasonable variable for a combined assessment of diagnostic accuracy and diagnostic confidence.

Comparing Treatments or Methods Using Receiver Operating Characteristic Summary Measures

ROC curves provide an easy way to compare the accuracy of two or more different diagnostic tests or methods. The direct comparisons for treatments or methods are by plotting the ROC curves on the same set of axes. If superiority or equivalence is the question of interest, one or more summary measures from the curves may be compared quantitatively using a statistical method appropriate for the design of the experiment producing the data.

Hanley and McNeil^[9] derived a nonparametric method for comparing the areas under two ROC curves by calculating asymptotic standard errors for the areas assuming independent approximately continuous distributions for the curves. They use the relationship between the AUC and the Wilcoxon statistic, w , to calculate the standard error of the area under the curve without distributional assumptions as below:

$$SE(w) = \sqrt{\frac{\theta(1-\theta) + (n_A - 1)(Q_1 - \theta^2) + (n_N - 1)(Q_2 - \theta^2)}{n_A n_N}}$$

where θ is the estimate of AUC; n_A and n_N are the number of abnormal and normal cases, respectively; Q_1 is the probability that two randomly chosen abnormal images (or patients) are both ranked with greater abnormal test results than a randomly chosen normal image (patient); and Q_2 is the probability that one randomly chosen abnormal image (patient) is ranked with greater abnormal result than two randomly chosen normal images (patients).

The standard errors may be used to test the difference between two areas (AUC_1 and AUC_2) that are derived based on two independent groups. The test statistic z that follows a standard normal distribution is given as below:

$$z = \frac{AUC_1 - AUC_2}{\sqrt{[SE(AUC_1)]^2 + [SE(AUC_2)]^2}}$$

A method for comparing two ROC curves arising from correlated data was proposed by Hanley and McNeil in 1983.^[12] They suggested calculating the area and standard error estimates for the individual curves in the same way as the independent case described earlier. The standard error for the difference of the two curves is then calculated as

$$SE(AUC_1 - AUC_2) = \sqrt{SE^2(AUC_1) + SE^2(AUC_2) - 2rSE(AUC_1)SE(AUC_2)}$$

The estimation of the correlation r between the two areas is a function of the correlations of the individual ratings calculated separately for diseased and nondiseased patients.

The test statistic for the paired case is therefore

$$z = \frac{AUC_1 - AUC_2}{\sqrt{[SE(AUC_1)]^2 + [SE(AUC_2)]^2 - 2r[SE(AUC_1)][SE(AUC_2)]}}$$

where r is the Pearson correlation between AUC_1 and AUC_2 .

DeLong et al.^[13] proposed a different nonparametric method for comparing two correlated ROC curves. Their method exploits the properties of the Mann-Whitney statistics, whose relationship to ROC areas has been mentioned previously. They pointed out that the Mann-Whitney statistics are part of the set of generalized U -statistics. They further derived a test statistics for the difference of two correlated ROC curves based on the generalized U -statistics.

Thompson and Zucchini^[6] proposed an analysis of variance (ANOVA) model to compare accuracy indices between different modalities. Here, the accuracy index may be defined as the true positive rate, the partial area under the ROC curve, the whole area under the curve, or some other predefined measure. Their model allows for multiple readers and includes components for modalities, between readers, and within readers.

Campbell^[14] recommended a different alternative to ROC area for use as an index in comparing two curves, which result from continuous measurements on the same set of subjects. The proposed test is based on the maximum distances between the two curves, similar to the Kolmogorov-Smirnov tests for agreement of distributions. Bandos et al.^[15] proposed an exact non-parametric permutation test for comparing AUCs from 2 correlated ROC curves. They also give an asymptotic version of the procedure.

Another alternative approach to analyze ROC areas was proposed by Venkatraman and Begg.^[16] They presented a distribution-free permutation test for comparing ROC curves based on continuous data from a paired design. Their method attempts to assess the equality of the actual curves rather than some derived index. Liu et al. proposed methods for assessing equivalence and non-inferiority of ROC curves from paired data.^[17] They propose using the “two one-sided tests” approach and employing bootstrapping techniques to approximate the sampling distributions. Li et al.^[18] developed a non-inferiority test for paired ROC curves based on partial areas. They use the concept of a generalized p -value to construct their test procedure.

Combining Sensitivities and Specificities from Several Clinical Trials—Meta-Analysis Using a Summary Receiver Operating Characteristic Curve

If several estimates for the sensitivity and specificity of a given test are available from different sources, it may be necessary to derive a single estimate from these values. Recognizing the interrelationship between these two quantities, the use of the averages of the sensitivity and specificity values is generally not recommended. The approach proposed by Moses et al.^[19] to handle this problem is the summary ROC curve. They proposed some methods to estimate the summaries of ROC curve and how to characterize their adequacy. The underlying assumptions of their methods are the independence of studies, and each study

should provide an estimated FPR and an estimated TPR. These rates are then converted into their logistic transforms, U and V , respectively. Then for each study $V - U$, the log odds ratio, and $V + U$ are calculated and plotted. A type of regression line is then fitted to these points, and the line is backtransformed into ROC space. This produces a curve in the unit square, which looks like a traditional ROC curve. It is then suggested that any estimates that are to be made from the summary ROC curve be based only on “relevant” values of TPR and FPR (TPR > 0.5 and FPR < 0.5 is put forth as a possibility).

Walter^[20] explored the use of partial areas under the SROC curve and concluded that this measure was more sensitive to heterogeneity than full AUCs. Chappell et al.^[21] review several models for performing SROC, and provide some guidance for when these methods are appropriate.

Some of the aforementioned methods in the previous sections and other more advanced methods are included in a text by Zhou, Obuchowski, and McClish.^[22]

Sample Size Calculation

Hanley and McNeil^[9] provide a method for estimating sample size for comparing the areas under two independent ROC curves, given that equal numbers of normal and abnormal can be obtained. The formula is given as below

$$n_N = n_A = \left[\frac{z_\alpha \sqrt{2V_1} + z_\beta \sqrt{V_1 + V_2}}{\delta} \right]^2$$

where $V_1 = Q_1 + Q_2 - 2\theta_1^2$, $V_2 = Q_1 + Q_2 - 2\theta_2^2$, $\delta = \theta_1 - \theta_2$, z_α and z_β are the upper 100 α and 100 β percentile points of a standard normal distribution. In V_1 , Q_1 and Q_2 are defined as $Q_1 = \theta_1/(2 - \theta_1)$, $Q_2 = 2\theta_1^2/(1 + \theta_1)$. In V_2 , $Q_1 = \theta_2/(2 - \theta_2)$, $Q_2 = 2\theta_2^2/(1 + \theta_2)$.

Obuchowski and McClish^[23] proposed a method for calculating sample size assuming a binormal ROC curve. In their method, the variance and covariance of the parameters a and b of the ROC curve are estimated based on the Taylor expansions and the derivation of large sample theory.

Obuchowski^[24] proposed a method for assessing the equivalence of diagnostic tests based on ROC curve methodology. Following ideas from bioequivalence in pharmacokinetic studies, the criteria of “population equivalence” and “individual equivalence” were developed for diagnostic equivalence. The estimates for the equivalency parameters were established and the confidence intervals were constructed by using the bootstrap methods for both criteria. Based on the results from a Monte Carlo simulation study, Obuchowski^[24] concluded that the power for detecting equivalence of ROC areas was reasonably close to the power for detecting a difference of δ in ROC areas. Therefore, similar numbers of patients for testing the equivalence and detecting a difference would be needed for the comparison of diagnostic tests.

An Example

In this example, the data set from Hanley and McNeil^[12] was used to illustrate the ROC analysis. The data set consists of ratings (from 1 = definitely normal to 6 = definitely abnormal) given to two modalities used on each of 112 phantoms. The purpose of this analysis is to study the accuracy of two computer algorithms (modalities) used in image reconstruction for computed tomography (CT). The data is illustrated (see table below) by the phantom status (normal, abnormal):

	Ratings with modality 2						
Ratings with modality 1	1	2	3	4	5	6	Total
Frequency counts of ratings by modality for normal CT phantoms							
1	9	3	0	0	0	0	12
2	17	9	2	0	0	0	28
3	3	4	1	0	0	0	8
4	3	2	2	1	0	0	6
5	3	1	0	2	0	0	4
6	0	0	0	0	0	0	0
Total	31	19	5	3	0	0	58
Frequency counts of ratings by modality for abnormal CT phantoms							
1	0	0	1	0	0	0	1
2	1	0	2	0	0	0	3
3	1	1	1	3	0	0	6
4	1	1	1	9	1	0	13
5	0	0	0	7	10	5	22
6	0	0	0	0	4	5	9
Total	3	2	5	17	15	10	54

The results of ROC analysis are summarized in the following table:

Modality	Slope	Intercept	Z_A	AUC	SE(AUC)	r	z
Modality 1	0.945	1.72	1.25	0.8945	0.03	0.40	1.41
Modality 2	0.467	1.70	1.54	0.9382	0.026		

In the table, r is the correlation of AUCs from two modalities, and z is the test statistic to test the null hypothesis that the difference between two areas is zero. Based on a significance level of 5%, it concluded that there is no difference in accuracy of two different computer algorithms used in image reconstruction for CT. The ROC curves are shown in Fig. 2.

SCIENTIFIC ISSUES

The utility of ROC curve analysis to demonstrate or illustrate the trade-off between sensitivity and specificity of diagnostic tests or instruments for signal detection has rarely if ever been questioned. It is the application of ROC methods for other purposes, such as demonstrating or comparing diagnostic efficacy of tests or methods, which has evoked criticism.

One source of controversy alluded to previously is the lack of agreement on a single summary measure. Although the total AUC uses all the information (points) on the ROC curve, it includes sensitivity, specificity pairs that are of little or no interest. It has been pointed out that tests that are clearly superior may have similar total AUCs to inferior tests.^[14] Variations such as partial AUC alleviate this feature to some extent, but the bounds of the area must be somewhat subjective. Likewise, single points based on a predetermined sensitivity or specificity value require some subjective choice of standard, and this choice for a given test sample may prove inappropriate (if it falls far out of the range of observed values, for example). Unfortunately,

Fig. 2 ROC curves for Hanley and McNeil data

there is no perfect summary measure that can characterize an entire ROC curve.

Other problems arising from the use of ROC curves to quantify the accuracy of diagnostic tests arise from the definition of sensitivity and specificity rather than from the construction of the curve. Whenever there is not a perfect dichotomy for the classification of test subjects, inconsistencies may arise in the calculation of these and/or other related predictive rates. Although a simple solution to this problem may seem to be just to force a dichotomy, it is not always practical to do this. In studies of diagnostic devices or contrast agents for these devices, a result such "not assessable" is often difficult to avoid even in the best of circumstances. Although it is possible to alter the classical definitions of sensitivity and specificity to reasonably accommodate this extra category, these altered rates invariably lead to problems with the related predictive rates and with the construction of the usual ROC curves.

As with all statistical methods, missing data create problems in ROC curve analysis that do not have perfect solutions. Leaving out partial observations (those where either the test value or the standard of reference are missing) is always open to criticism because it leads to possibly biased results. Any attempt to include partial data utilizes direct or implied imputations, which must rely on some set of assumptions. Because the validity of these assumptions is always open to debate for any given situation, any method to handle missing data in ROC curve analysis may be criticized. This is not to say that they should not be used, because when there is a substantial amount of missing data, better estimates will most likely result from the methods using all cases. One method, proposed by Zhou and Gatsonis^[25] for handling a certain type of missing ROC data utilizes a derived covariance matrix of nonparametric estimators of ROC AUCs for incomplete paired data. They then use this estimator to test the difference of the areas using all available cases.

CONCLUSION

Two assumptions had been used for evaluating and comparing sensitivity and specificity in diagnostic tests. They are the following: (i) diagnostic tests are independent given the disease status and (ii) the gold standard (reference) is error free. For cases where the assumptions are not valid, several approaches have been investigated. Qu and Hadgu^[26] suggested some statistical methods for these cases that: diagnostic tests are correlated, gold standard is imperfect, and diagnostic tests are correlated when the gold standard is imperfect. Alternatively, Baker et al.^[27] proposed the methods for estimating sensitivity and specificity without a gold standard.

Another clinical practice in diagnostic imaging is that the accuracy of an imaging study is very often to be evaluated by multiple readers or/and patients to be examined

by multiple modalities. This was investigated by Toledano and Gatsonis,^[28] where the application of analysis of ROC data from multiple interpretations of the same diagnostic study and from the examination of the same patients with multiple diagnostic modalities was to be performed. They proposed the use of ordinal regression models in conjunction with generalized estimating equations to analyze the correlated ROC data.

Pepe^[29] interprets each point on the ROC curve as a conditional probability of a test result from a random diseased subject exceeding that from a random nondiseased subject. The ROC curves were then estimated by generalized linear model procedures. It has been observed that many disease outcomes are time dependent. Therefore, it is more appropriate to consider the ROC curve as a function of time. Heagerty et al.^[30] proposed the statistical method for time-dependent ROC curves for survival data.

The overview of ROC analysis for evaluation of the performance of diagnostic medical products can be found in Chow and Shao.^[31]

Abstract

The objective of sample size calculation is to select an appropriate sample size so that not only the Type I error probability can be controlled under the specified level when the null hypothesis is true, but also to assure sufficient power for detection of a clinically meaningful difference when the alternative hypothesis is true. This entry reviews the sign test for comparing median and tests for independence and also provides simulation results and numerical examples.

INTRODUCTION

Sample size calculation plays an important role in clinical research.^[1] The objective of sample size calculation is to select an appropriate sample size so that not only the Type I error probability can be controlled under the specified level when the null hypothesis is true, but also to assure sufficient power for detection of a clinically meaningful difference when the alternative hypothesis is true.

In biopharmaceutical research, various nonparametric tests are often used to serve different scientific purposes when parametric assumptions are not met.^[2] Four non-parametric tests including sign test, one-sample Wilcoxon's test, two-sample Wilcoxon's test, and Kendall's test for independence are commonly used.

OVERVIEW

Under the null hypothesis, these test statistics are asymptotically distributed as a standard normal distribution. The knowledge of their distribution under the alternative hypothesis is essential to derive formula for sample size calculation. To achieve this objective, two different approaches are usually considered.

One is to derive the asymptotic distribution of the test statistics under the so-called local alternatives when the null hypothesis is false.^[3] Local alternative assumes that an appropriately defined difference between the true parameter and the reference value (or control) vanish to 0 at the speed of $n^{-1/2}$. A practical consequence of this assumption is that the test statistic's asymptotic variance under the local alternative stays the same as the asymptotic variance under the null hypothesis. In other words, the effect of the local alternative is just changing the mean of the

asymptotic distribution of the testing statistic but not its variance. The merit of this method is that the test statistic has a nondegenerate asymptotic distribution under the alternative hypothesis. Hence a formula for sample size calculation can be easily derived. In practice, the alternative hypothesis is usually fixed and they do not vanish to 0 as sample size goes larger. As a result, the idea of local alternative may not be easily understood and accepted by scientists. This induces another approach based on fixed alternatives.

Fixed alternative approach assumes that the appropriately defined difference between the true parameter and the reference (or control) stays fixed under the alternative hypothesis.^[4,5] With appropriate normalization and approximation, explicit formula for sample size calculation based on the four nonparametric tests can be obtained. The merit of this fixed alternative approach is that it is easily understood and accepted in practice. When the alternative hypothesis is fixed, one may expect the fixed-alternative-based formulae to have better precision than the local-alternative-based formula. The drawback of this approach is that it usually requires the knowledge of more parameters than the local-alternative-based formula. In practice, the parameters used to estimate the sample size are usually unknown. As a result, it has to be estimated from pilot studies, historical data, or literatures. As a result, the fact that more parameters need to be estimated for fixed-alternative-based formulae may imply less reliable sample size estimation if the parameter estimates themselves are not accurate enough.

In the next section, the sign test for comparing median is studied. In the succeeding sections, one-sample Wilcoxon's test, two-sample Wilcoxon's test, and Kendall's test for independence are discussed. In each section, formulae for sample size calculation based on both local

and fixed alternatives are derived. For illustration purposes, simulation results and numerical examples are also presented. For technical details, the readers should refer to Refs. [3–5].

SIGN TEST

Introduction

Let $x_1, \dots, x_n$ be independent and identically distributed continuous random samples with median θ , i.e., $P(x_i \leq \theta) = 0.5$. In biopharmaceutical research, it is often of interest to test the following hypothesis:

$$H_0: \theta = \theta_0 \quad \text{vs.} \quad H_1: \theta \neq \theta_0$$

Define $Z_i = I(x_i > \theta_0)$, where $I(\cdot)$ is the indicator function. Let $p = P(Z_i = 1)$, then the above hypotheses become

$$H_0: p = 0.5 \quad \text{vs.} \quad H_1: p \neq 0.5$$

As a result, we may consider the following test statistic

$$T = 2\sqrt{n}(\bar{z} - 0.5)$$

where $\bar{z}$ is the sample mean of $z_1, \dots, z_n$. Under the null hypothesis, T is asymptotically distributed as a standard normal distribution. As a result, we reject the null hypothesis at the α level of significance if $|T| > z_{\alpha/2}$.

Fixed Alternative

Under the fixed alternative hypothesis that $p \neq p_0$, the power of the above test is approximately given by

$$\Phi\left(\frac{\sqrt{n}|p - 0.5| + 0.5z_{\alpha/2}}{\sqrt{p(1-p)}}\right)$$

As a result, the sample size needed for achieving a desired power of $1 - \beta$ can be obtained by solving the following equation

$$\frac{\sqrt{n}|p - 0.5| + 0.5z_{\alpha/2}}{\sqrt{p(1-p)}} = -z_{\beta}$$

This leads to

$$n_f = \left(\frac{0.5z_{\alpha/2} + z_{\beta}\sqrt{p(1-p)}}{p - 0.5}\right)^2$$

Local Alternative

Under a local alternative, it is assumed that the difference between p and 0.5 is sufficiently small so that

$$\sqrt{p(1-p)} \approx 0.5$$

Thus n_f can be approximated by

$$n_l = \frac{(z_{\alpha/2} + z_{\beta})^2}{4(p - 0.5)^2}$$

which leads to the formula given in Ref. [3].

A Simulation Study

A simulation study was conducted to evaluate the performance of the derived sample size formulae for both fixed and local alternatives. x_i 's are simulated as independent and identically continuous responses with $P(x_i \leq \theta_0) = p$. For each value of p , sample sizes needed to achieve 80% power at the 5% level of significance are estimated. Then, using the calculated sample size, the true power is simulated based on the 10,000 simulations. Table 1 summarizes the results from the simulation. As it can be seen, the difference between the sample sizes determined based on fixed and local alternatives are very small. When the estimated sample size is relatively large, they have very similar performance while the local alternative approach is a little bit more conservative. When the estimated sample size is relatively small, the fixed alternative approach performs slightly better than the local alternative approach.

An Example

To illustrate the use of sample size formulae derived above, we consider an example concerning a clinical trial for evaluation of the effect of a test drug with some continuous clinical endpoint. Suppose that the investigator is interested in testing whether 0 is the median of this distribution. Let p denote the true probability of this continuous response to be less than 0. Then, it is equivalent to test whether $p = 0.5$. Suppose that, based on historical data, it is estimated that $p = 0.7$; hence the sample size needed to achieve an 80% power for detection of a clinically meaningful improvement. On the other hand, the local alternative approach gives

$$\begin{aligned} n_f &= \left(\frac{0.5z_{\alpha/2} + z_{\beta}\sqrt{p(1-p)}}{p - 0.5}\right)^2 \\ &= \left(\frac{0.5 \times 1.96 + 0.84\sqrt{0.7(1-0.7)}}{0.7 - 0.5}\right)^2 \\ &= 46.58 \approx 47 \end{aligned}$$

Thus a total of 47 subjects are needed to have an 80% power to reject the null hypothesis. On the other hand, using a local alternative formula, it can be obtained that

$$n_l = \frac{(z_{\alpha/2} + z_{\beta})^2}{4(p - 0.5)^2} = \frac{(1.96 + 0.84)^2}{4(0.7 - 0.5)^2} \approx 49$$

Table 1 Sample Size n and Actual Power for Sign Test with Estimated p with Power -0.80 {10,000 Simulations}

ONE-SAMPLE WILCOXON'S TEST

Introduction

Let $x_1, \dots, x_n$ be independent and identically distributed samples generated from the following model

$$x_i = \theta + e_i, \quad i = 1, \dots, n$$

where θ is the unknown location parameter and the e_i 's are random error with a distribution symmetric about 0. The hypothesis of interest is given by

$$H_0: \theta = 0 \quad \text{vs.} \quad H_1: \theta \neq 0$$

To test the above hypotheses, one-sample Wilcoxon's test can be used. Let R_i be the rank of $|x_i|$ in $\{|x_1|, \dots, |x_n|\}$. Define

$$\psi_i = \begin{cases} 1 & \text{if } x_i > 0 \\ 0 & \text{if } x_i < 0 \end{cases}$$

where $i = 1, \dots, n$. Then, the statistic

$$T^+ = \sum_{i=1}^n R_i \psi_i$$

is the sum of the positive signed ranks. It can be verified that under the null hypothesis,

$$T = \frac{T^+ - n(n+1)/4}{\sqrt{n(n+1)(2n+1)/24}}$$

is asymptotically distributed as a standard normal distribution. Therefore we reject the null hypothesis at the α level of significance if $|T| > z_{1-\alpha/2}$.

Fixed Alternative

To determine the sample size under a fixed alternative, we need to evaluate the mean and variance of T^+ under an alternative hypothesis. It can be verified⁴ that the mean and variance of T^+ are given by

$$\begin{aligned} E(T^+) &= np_1 + n(n-1)p_2 \\ \text{var}(T^+) &= np_1(1-p_1) + n(n-1) \\ &\quad \times (p_1^2 - 4p_1p_2 + 3p_2 - 2p_2^2) \\ &\quad + n(n-1)(n-2) \\ &\quad \times (p_3 + 4p_4 - 4p_2^2) \end{aligned}$$

Where

$$\begin{aligned} p_1 &= P(x_1 > 0) \\ p_2 &= P(x_1 \geq |x_2|) \\ p_3 &= P(x_1 \geq |x_2|, x_1 \geq |x_3|) \\ p_4 &= P(x_1 \geq x_2 \geq |x_3|) \end{aligned}$$

Let $\sigma_+^2 = \text{var}(T^+)$. Then, under the alternative hypothesis, T^+ can be approximated by a normal random variable with mean $E(T^+) = np_1 + n(n-1)p_2$ and variance σ_+^2 . As a result, the power of the one-sample Wilcoxon's test can be approximated by

$$\Phi\left(\frac{z_{\alpha/2}/\sqrt{12} + \sqrt{n}|1/4 - p_2|}{\sqrt{p_3 + 4p_4 - 4p_2^2}}\right)$$

Hence the sample size required for achieving a desired power of $1 - \beta$ can be obtained by solving the following equation

$$\frac{z_{\alpha/2}/\sqrt{12} + \sqrt{n}|1/4 - p_2|}{\sqrt{p_3 + 4p_4 - 4p_2^2}} = -z_\beta$$

This gives

$$n_f = \left(\frac{z_{\alpha/2}/\sqrt{12} + z_\beta\sqrt{p_3 + 4p_4 - 4p_2^2}}{(1/4 - p_2)^2}\right)^2$$

Local Alternative

Under a local alternative, the difference between the null hypothesis and the alternative hypothesis is sufficiently small. As a result, the following approximations hold:

$p_2 \approx 1/4$, $p_3 \approx 1/6$, $p_4 \approx 1/24$. It follows that n_f can be approximated by

$$n_f = \frac{(z_{\alpha/2} + z_\beta)^2}{3(0.5 - 2p_2)^2}$$

If we define $p' = P(x_1 + x_2 \geq 0)$, then it follows that

$$\begin{aligned} p' &= P(x_1 + x_2 \geq 0) \\ &= 2P(x_1 + x_2 \geq 0 \text{ and } |x_1| \geq |x_2|) \\ &= 2P(x_1 \geq |x_2|) = 2p_2 \end{aligned}$$

As a result, n_f can be expressed as

$$n_f = \frac{(z_{\alpha/2} + z_\beta)^2}{3(p' - 0.5)^2}$$

which leads to the formula given in Ref. [3].

A Simulation Study

A simulation study was conducted to evaluate the performance of the derived sample size formulae for both fixed and local alternatives, x_i 's are generated from normal population with mean θ and variance 1. The p_i 's are estimated by the Monte Carlo method based on a sample of size 100,000. The estimated values of p_i 's are used to determine the sample size based on both fixed and local alternatives. Then, using the calculated sample size, the true power is simulated based on the 10,000 simulations. Table 2 summarizes the results from the simulation. As the table shows, the difference between the sample sizes determined based on fixed and local alternatives are very small. When the estimated sample size is relatively large, they have very similar performance while the local alternative approach is a little bit more conservative. When the estimated sample size is relatively small, the fixed alternative approach performs slightly better than the local alternative approach.

An Example

To illustrate the use of sample size formulae derived above, we consider an example concerning a clinical trial for evaluation of the effect of a test drug with some continuous clinical endpoint. Each patient participating in the trial will have two measurements. One is before the treatment, which serves as a baseline value, and the other one is after the treatment. The difference of those two measurements will serve as the primary efficacy endpoint and hence will be used to evaluate the possible treatment effect of the test drug. When there is no treatment effect, the distribution of the pretreatment and posttreatment should be the same. As a result, it is reasonable to assume that under the null hypothesis,

0.440	0.671	0.369	0.258	0.087	43	0.790	47	0.814
0.445	0.673	0.368	0.257	0.085	43	0.789	48	0.839
0.450	0.674	0.368	0.257	0.086	43	0.804	47	0.831
0.455	0.675	0.368	0.256	0.087	44	0.816	48	0.855
0.460	0.677	0.371	0.258	0.086	40	0.789	45	0.830
0.465	0.678	0.372	0.260	0.089	41	0.815	44	0.836
0.470	0.682	0.373	0.261	0.088	39	0.789	44	0.850
0.475	0.684	0.377	0.265	0.091	37	0.780	41	0.823
0.480	0.683	0.375	0.263	0.090	38	0.803	42	0.836
0.485	0.685	0.378	0.263	0.090	36	0.797	41	0.845
0.490	0.686	0.376	0.262	0.089	37	0.808	42	0.854
0.495	0.691	0.379	0.265	0.091	35	0.793	40	0.849
0.500	0.692	0.378	0.263	0.091	36	0.804	40	0.857

0 is the median of our primary efficacy endpoint. Historical data show that the distribution of the endpoint cannot be well approximated by normal distribution or other standard parametric distribution. On the other hand, it is also noted that the treatment effect (if exists) usually do not change the shape of the distribution of the clinical endpoint; instead, it only causes certain shift in the relative location of the distribution. As a result, the one-sample Wilcoxon's test can be used to evaluate the possible treatment effect. Suppose that based on historical data, it has been estimated that $p_2 = 0.360$, $p_3 = 0.252$, and $p_4 = 0.083$. Hence the sample size needed to achieve an 80% power for detection of a clinically meaningful improvement is given by

$$\begin{aligned}
 n_f &= \frac{\left(z_{\alpha/2}/\sqrt{12} + z_{\beta}\sqrt{p_3 + 4p_4 - 4p_2^2}\right)^2}{(1/4 - p_2)^2} \\
 &= \frac{(1.96/\sqrt{12} + 0.84\sqrt{0.252 + 4 \times 0.083 - 4 \times 0.360^2})^2}{(0.360 - 0.252)^2} \\
 &= 52.29 \approx 54
 \end{aligned}$$

Thus a total of 53 subjects are needed. On the other hand, the local alternative approach gives

$$n_l = \frac{(z_{\alpha/2} + z_{\beta})^2}{3(p' - 0.5)^2} = \frac{(1.96 + 0.84)^2}{3(2 \times 0.36 - 0.5)^2} = 53.99 \approx 54$$

TWO-SAMPLE WILCOXON'S TEST

Introduction

Let $x_i, i=1, \dots, n_1$ and $y_j, j=1, \dots, n_2$ be two independent and identically distributed random samples, it is assumed that $x_i (i=1, \dots, n_1)$ and $y_j (j=1, \dots, n_2)$ come from the same type of symmetric distribution but with different location parameter θ . The primary objective is to investigate whether the location parameter θ equals to 0, i.e.,

$$H_0: \theta = 0 \quad \text{vs.} \quad H_1: \theta \neq 0$$

To test the above hypotheses by Wilcoxon's rank sum test, we first order the $N = n_1 + n_2$ observations from least to greatest and let R_i denote the rank of y_i in this ordering. Let

$$W = \sum_{i=1}^{n_2} R_i$$

where R_i denotes the order of y_i in the total samples. Consider the following test statistic

$$W^* = \frac{W - E(W)}{\sqrt{\text{var}(W)}} = \frac{W - 0.5n_2(n_2 + n_1 + 1)}{\sqrt{n_1n_2(n_1 + n_2 + 1)/12}}$$

When sample sizes n_1 and n_2 are both sufficiently large, W^* is asymptotically distributed as a standard normal distribution when the null hypothesis is true. Therefore we reject H_0 at the α asymptotic level of significance if $|W^*| \geq z_{\alpha/2}$.

Fixed Alternative

Under a fixed alternative, the power of the two-sample Wilcoxon's test can be approximated by

$$\Phi \left(\frac{z_1 - \alpha/2 \sqrt{\kappa(1+\kappa)/12} + \sqrt{n_2\kappa|1/2 - p_1|}}{\sqrt{\kappa^2(p_2 - p_1^2) + \kappa(p_3 - p_1^2)}} \right)$$

where $\kappa = \lim(n_1/n_2)$ and

$$\begin{aligned} p_1 &= P(y_1 \geq x_1) \\ p_2 &= P(y_1 \geq x_1 \text{ and } y_1 \geq x_2) \\ p_3 &= P(y_1 \geq x_1 \text{ and } y_2 \geq x_1) \end{aligned}$$

For technical details, see Refs. [4,5]. As a result, the sample size needed to achieve the desired power of $1 - \beta$ can be obtained by solving the following equation

$$\frac{z_{\alpha/2} \sqrt{\kappa(1+\kappa)/12} + \sqrt{n_2\kappa(1/2 - p_1)}}{\sqrt{\kappa^2(p_2 - p_1^2) + \kappa(p_3 - p_1^2)}} = -z_\beta$$

This leads to (see below)

Local Alternative

Under a local alternative, the difference between the null hypothesis and the alternative hypothesis is sufficiently small. Thus the following approximations hold: $p_1 \approx 1/2$, $p_2 \approx 1/3$, and $p_3 \approx 1/3$. As a result, it follows that n_f can be approximated by

$$n_f = \frac{(1+\kappa)^2 (z_{\alpha/2} + z_\beta)^2}{12\kappa(p_1 - 1/2)^2}$$

Define $c = n_1/(n_1 + n_2) = 1/(1 + \kappa)$, it follows that

$$n_f = \frac{(z_{\alpha/2} + z_\beta)^2}{12c(1-c)(p_1 - 1/2)^2}$$

which leads to the formula given in Ref. [3].

A Simulation Study

A simulation study was conducted to evaluate the performance of the derived sample size formulae for both fixed and local alternatives. x_i 's are generated from normal population with mean 0 and variance 1, y_j 's are generated from normal population with mean θ and variance 1. The sample size ratio κ is chosen to be 1. The p_i 's are estimated by the Monte Carlo method based on a sample of size 100,000. The estimated values of p_i 's are used to determine the sample size based on both fixed and local alternatives. Using the calculated sample size, the true power is simulated based on 10,000 simulations. The results are given in Table 3. From the table, we can see that the difference between the sample sizes determined based on fixed and local alternatives are very small. When the estimated sample size is relatively large, they have very similar performance while the local alternative approach is a little bit more conservative. When the estimated sample size is relatively small, the fixed alternative approach performs slightly better than the local alternative approach.

An Example

To illustrate the use of sample size formulae derived above, we consider an example concerning a clinical trial for evaluation of the effect of a test drug with some continuous clinical endpoint. The historical data shows that the distribution of the endpoint cannot be well approximated by normal distribution or other standard parametric distribution. On the other hand, it is also noted that the treatment effect (if exists) usually do not change the shape of the distribution of the clinical endpoint; instead, it only causes certain shift in the relative location of the distribution. As a result, the two-sample Wilcoxon's test can be used to evaluate the possible treatment effect.

0.675	0.680	0.534	0.532	39	0.813	41	0.836
0.680	0.681	0.535	0.535	38	0.816	40	0.829
0.685	0.685	0.538	0.538	37	0.808	39	0.835
0.690	0.688	0.542	0.540	35	0.798	37	0.812
0.695	0.689	0.543	0.542	35	0.797	37	0.817
0.700	0.690	0.544	0.545	34	0.790	37	0.829

$n_1 = \kappa n_2$ and

$$n_2 = \frac{\left(z_{\alpha/2} \sqrt{\kappa(\kappa+1)/12} + z_{\beta} \sqrt{\kappa^2(p_2 - p_1^2) + \kappa(p_3 - p_1^2)} \right)^2}{\kappa^2(1/2 - p_1)^2}$$

Let $n_f = n_1 + n_2$, it follows that

$$n_f = \frac{(1 + \kappa) \left(z_{\alpha/2} \sqrt{\kappa(\kappa+1)/12} + z_{\beta} \sqrt{\kappa^2(p_2 - p_1^2) + \kappa(p_3 - p_1^2)} \right)^2}{\kappa^2(1/2 - p_1)^2}$$

The null hypothesis of interest is the one of no treatment difference. Suppose that based on historical data, it has

been estimated that $p_1 = 0.40$, $p_2 = 0.25$, and $p_3 = 0.25$. Hence the sample size needed to achieve an 80% power can be estimated by

$$\begin{aligned} n_f &= \frac{2 \left(z_{\alpha/2} / \sqrt{6} + z_{\beta} \sqrt{p_2 + p_3 - 2p_1^2} \right)^2}{(1/2 - p_1)^2} \\ &= \frac{2 \left(1.96 / \sqrt{6} + 0.84 \sqrt{0.25 + 0.25 - 2 \times 0.40^2} \right)^2}{(0.50 - 0.40)^2} \\ &= 267.52 \approx 268 \end{aligned}$$

Hence a total of 268 subjects are needed to have an 80% power for detection of a clinically meaningful

difference. On the other hand, the local alternative approach gives

$$\begin{aligned} n_l &= \frac{(z_{\alpha/2} + z_\beta)^2}{12c(1-c)(p_1 - 1/2)^2} \\ &= \frac{(1.96 + 0.84)^2}{12 \times 0.5(1 - 0.5)(0.4 - 0.5)^2} \\ &= 261.33 \approx 262 \end{aligned}$$

KENDALL'S TEST OF INDEPENDENCE

Introduction

In practice, it is often of interest to test if two continuous responses received from each subject (e.g., the baseline value and the posttreatment value) are actually independent of each other. For such data, if a bivariate normal assumption can be made, then testing independence becomes the problem of testing whether the correlation coefficient equals to 0. However, in many situations, this assumption does not hold. As a result, a certain nonparametric test for independence becomes desirable.

Let $(x_i, y_i), i = 1, \dots, n$, be the n independent and identically distributed bivariate observations from the n subjects involved in a clinical trial. To obtain a nonparametric test for independence between x_i and y_i , define

$$\tau = 2P((x_1 - x_2)(y_1 - y_2) > 0) - 1$$

where τ is the so-called Kendall coefficient. A necessary requirement for the independence of x_i and y_i is that $\tau = 0$. As a result, whether x_i and y_i are independent can be tested by considering the hypothesis $H_0: \tau = 0$. Under the null hypothesis, a nonparametric test can be obtained as follows. First, for $1 \leq i < j \leq n$, calculate $\zeta(x_i, x_j, y_i, y_j)$, where

$$\zeta(a, b, c, d) = \begin{cases} 1 & \text{if } (a - b)(c - d) > 0 \\ -1 & \text{if } (a - b)(c - d) < 0 \end{cases}$$

Consider

$$K = \sum_{i=1}^{n-1} \sum_{j=i+1}^n \zeta(x_i, x_j, y_i, y_j)$$

Consider the following testing statistics

$$K^* = \frac{K - E(K)}{\sqrt{\text{var}(K)}} = K \left[\frac{n(n-1)(2n+5)}{18} \right]^{-1/2}$$

It can be shown that when sample size n is sufficiently large, K^* is asymptotically distributed as a standard normal distribution. Hence we would reject the null hypothesis at the α asymptotic level of significance for large samples if $|K^*| \geq z_{\alpha/2}$.

Fixed Alternative

Define

$$\begin{aligned} p_1 &= P((x_1 - x_2)(y_1 - y_2) > 0) \\ p_2 &= P((x_1 - x_2)(y_1 - y_2)(x_1 - x_3)(y_1 - y_3) > 0) \end{aligned}$$

Under the fixed alternative hypothesis that $p_1 \neq 0.5$ and assuming n is sufficiently large, the power of the above test can be approximated by

$$\Phi \left(\frac{z_{\alpha/2}/3 + \sqrt{n} |p_1 - 1/2|}{\sqrt{2p_2 - 1 - (2p_1 - 1)^2}} \right)$$

For the details of the above approximation, please refer to Ref. [4]. Hence the sample size needed to achieve a desired power of $1 - \beta$ can be obtained by solving the following equation

$$\frac{z_{\alpha/2}/3 - \sqrt{n} (p_1 - 1/2)}{\sqrt{2p_2 - 1 - (2p_1 - 1)^2}} = -z_\beta$$

This yields

$$n_f = \frac{\left[z_{\alpha/2}/3 + z_\beta \sqrt{2p_2 - 1 - (2p_1 - 1)^2} \right]^2}{(p_1 - 1/2)^2}$$

Local Alternative

Under a local alternative, the difference between the null hypothesis and the alternative hypothesis is sufficiently small. As a result, the following approximations hold: $p_1 \approx 1/2$ and $p_2 \approx 5/9$. It follows that n_l can be approximated by

$$n_l = \frac{(z_{\alpha/2} + z_\beta)^2}{9(p_1 - 1/2)^2}$$

which leads to the formula given in Ref. [3].

A Simulation Study

A simulation study was conducted to evaluate the performance of the derived sample size formulae for both fixed and local alternatives. (x_i, y_i) 's are generated in the following way: For any given correlation coefficient p , let

$$x_i = u_i \text{ and } y_i = \frac{p}{\sqrt{1-p^2}} u_i + v_i$$

Table 4 Sample Size n and Actual Power for Independence with Correlation Coefficient p and Estimated p with Power = 0.80 (10,000 Simulations)

p	p_1	p_2	Fixed alternative		Local alternative	
			n	True power	n	True power

0.440	0.646	0.588	38	0.766	40	0.791
0.445	0.645	0.587	38	0.773	41	0.803
0.450	0.651	0.588	35	0.752	38	0.780

where u_i and v_i are random samples generated from the standard normal distribution. The p_i 's are estimated by the Monte Carlo method based on a sample of size 100,000. The estimated values of p_i 's are used to determine the sample size based on both fixed and local alternatives. Then, using the calculated sample size, the true power is simulated based on 10,000 simulations. Table 4 summarizes the results. From the table, we can see that the difference between the sample sizes determined based on fixed and local alternatives are very small while the sample size determined by local alternative seems to be

slightly better than the sample size determined by fixed alternative.

An Example

Suppose x and y are two continuous responses in a clinical trial, where x represents the pretreatment measurement and y represents the posttreatment measurement. Past experiences show that these data cannot be fitted well by any standard parametric distribution. As a result, Kendall's test for independence is recommended to test whether there is

an association between the pretreatment and posttreatment measurement. Based on historical data, it is estimated that $p_1 = 0.60$ and $p_2 = 0.58$. Hence the sample size required for achieving an 80% power can be obtained as follows

$$\begin{aligned} n_f &= \frac{\left(z_{\alpha/2}/3 + z_\beta \sqrt{2p_2 - 1 - (2p_1 - 1)^2}\right)^2}{(p_1 - 1/2)^2} \\ &= \frac{\left(1.96/3 + 0.84 \sqrt{2 \times 0.58 - 1 - (1.20 - 1)^2}\right)^2}{(0.60 - 0.50)^2} \\ &= 89.17 \approx 90 \end{aligned}$$

Thus a total of 90 subjects are needed to achieve an 80% power to confirm the association between x and y . On the other hand, the local alternative approach gives

$$\begin{aligned} n_l &= \frac{\left(z_{\alpha/2} + z_\beta\right)^2}{9(p_1 - 0.5)^2} \\ &= \frac{(1.96 + 0.84)^2}{9(0.60 - 0.50)^2} \\ &= 87.11 \approx 88 \end{aligned}$$

CONCLUSION

In biopharmaceutical research, nonparametric methods are often used when the underlying distribution

assumption for parametric methods are not met. In this article, formulae for sample size calculation based on four commonly used nonparametric tests are derived. These tests include sign test, one-sample Wilcoxon's test, two-sample Wilcoxon's test, and Kendall's test of independence. Sample size formulae are derived under both local and fixed alternatives. Extensive simulations were performed to study the empirical performance of sample size derived under both fixed alternative and local alternative. Examples are given to illustrate the use of the derived formulae.

Sample Size Calculation: Survival Data

Qi Jiang and Steven Snapinn

Merck Research Laboratories, West Point, Pennsylvania, U.S.A.

Boris Iglewicz

Temple University, Philadelphia, Pennsylvania, U.S.A.

Abstract

Sample size calculation is an important aspect of the design of any clinical trial. This entry describes basic approaches for sample size calculation in survival studies and also discusses sample size calculation for group sequential survival trials.

INTRODUCTION

Accurate determination of the required sample size for survival studies involves various factors that either are unique to these studies or are not typically considered in non-survival studies. These include the survival distributions, censoring distributions, patient accrual patterns, rates of loss to follow-up and noncompliance, and lag in the treatment effect. In addition, the sample size calculation should be specific to the planned analysis approach. This article reviews these factors and the methods that have been proposed to account for them.

OVERVIEW

Sample size calculation is an important aspect of the design of any clinical trial. If the sample is too small there may be insufficient information to detect a true treatment difference, whereas if the sample is too large exposure to an experimental treatment and cost will be unnecessarily high. Accurate determination of sample size requires specification of an appropriate study endpoint, a statistical model and design parameters, the clinically meaningful difference, Type I error, and power. In addition, there are some unique factors affecting sample size in trials involving a time-to-event endpoint, as described below.

Patients typically enroll in a survival trial during a recruitment period. This process is referred to as “staggered entry” to distinguish it from simultaneous enrollment of all patients, and it can have an important impact on sample size requirements. Principal interest during follow-up concerns the time of occurrence of a particular “event” or “endpoint,” which could be death or some other clinical observation. In general, patients are followed from randomization through termination of the trial or an endpoint, whichever occurs first. Those patients who complete the study without experiencing an event

are said to be “right-censored.” The event and censoring distributions also play an important role in sample size determination.

Often some patients do not follow the prescribed protocol for the trial duration. Patients may be withdrawn from follow-up despite the investigators’ efforts; for example, they may refuse to be followed or they may die from an unrelated cause. These “lost to follow-up” patients are not under surveillance for the remainder of the trial. Other patients discontinue the experimental treatment (“drop-outs”) or switch from the control to the experimental treatment (“drop-ins”). We assume that drop-outs and drop-ins (“noncompliant” patients) continue in follow-up. One possible analysis approach is to censor these patients at the time of noncompliance; however, this results in effective derandomization and can bias the treatment comparison. The intention-to-treat analysis avoids this bias by including complete follow-up of all patients, regardless of premature discontinuation of treatment. However, by including complete follow-up in the analysis the treatment effect may be diluted. Careful assessment of the proportion of noncompliant patients is an important component of sample size calculation.

In some clinical trials the treatments reach full effectiveness immediately, whereas in other cases the full treatment effect requires a period of time, known as “lag time.” Several models have been considered, including a linear increase and a threshold model in which the full treatment effect begins after a delay. While the concept of lag usually refers to the onset of the treatment effect (“onset lag”), it may also refer to the loss of treatment effect following discontinuation of study treatment (“decay lag”).

There are three typical types of study termination criteria: 1) “fixed follow-up duration” for each patient; 2) “common closing date,” chosen based on predicted event rates used to calculate power; 3) “fixed number of events,” where the study continues until a prespecified

number of events are observed. For trials with staggered entry, a common closing date or fixed number of events will result in variable durations of follow-up. The fixed endpoint approach has the advantage of guaranteeing the desired power regardless of any discrepancy between the assumed and actual event rates. Given the critical importance of the number of observed events in survival studies, calculation of sample size is actually a matter of finding the right balance between sample size and study duration to produce the required number of events.

In the next sections, we describe three basic approaches for sample size calculation in survival studies, approaches based on the binomial distribution, exponential survival distributions, and semiparametric models such as those that are the basis for the logrank test and Cox proportional hazards regression. Within each section, we describe adjustments to these models proposed to account for the design issues described above. We also discuss sample size calculation for group sequential survival trials and commonly used software packages.

SAMPLE SIZE CALCULATION BASED ON THE BINOMIAL DISTRIBUTION

Although the analysis of survival studies involves methods designed for time-to-event data, the sample size calculation for a study of duration T years is sometimes based on the anticipated T -year event rates in the control group (p_c) and the experimental group (p_e), without consideration of the survival distributions. Assuming equally-sized groups and a one-tailed test of $H_0: p_e = p_c$, the total sample size N can be calculated using the following asymptotic formula:

$$N = \frac{2 \times [Z_\alpha \sqrt{2\bar{p}(1-\bar{p})} + Z_\beta \sqrt{p_e(1-p_e) + p_c(1-p_c)}]^2}{(p_e - p_c)^2} \quad (1)$$

where $\bar{p} = (p_e + p_c)/2$, and Z_α and Z_β are normal deviates associated with α and β .^[1] (In general, throughout this article, formulas involving Z_α refer to one-tailed tests, and formulas involving $Z_{\alpha/2}$ refer to two-tailed tests.) Adjustments for noncompliance and other factors typically involve first estimating effective event rates, and then plugging them into the above formula.

Schork and Remington^[2] estimated effective event rates by taking into account yearly event rates and noncompliance patterns, assuming time invariance and no decay lag. Halperin, Rogot, Gurian, and Ederer^[1] (hereinafter HRGE) estimated the effective event rate in the experimental group by allowing for a linear onset lag and for drop-outs, based on modeling the distribution of time to drop-out. Decay lag and drop-in were not considered. Wu, Fisher, and DeMets^[3] (hereinafter WFD) generalized HRGE by dividing the annual time intervals into subintervals and allowing for time-dependent drop-out and event rates. They also allowed for drop-ins (which could return to the

control treatment at a later date), unequal sample sizes, and linear onset and decay lags.

In 1986, Lakatos^[4] estimated effective event rates by using a discrete nonstationary Markov process that allows for stratification, time-dependent event rates, noncompliance, loss to follow-up, staggered entry, and onset and decay lag. A typical transition matrix for the experimental group is given below:

	L	E	C_1	C_2	C_3	D_0	D_1	D_2
L	1		l	l	l	l	l	l
E		1	p_{e_1}	p_{e_2}	p_{e_3}	p_{e_0}	p_{e_1}	p_{e_2}
C_1						b		
C_2			$1 - \Sigma$				b	
C_3				$1 - \Sigma$	$1 - \Sigma$			b
D_0			c			$1 - \Sigma$	$1 - \Sigma$	
D_1				c				$1 - \Sigma$
D_2					c			

State L denotes lost to follow-up, state E denotes an event, states C_i denote patients in follow-up with event rate p_{e_i} ($i = 1, 2, 3$), and states D_i denote patients in follow-up subsequent to drop-out with event rate p_{e_i} ($i = 0, 1, 2$). The multiple states C_i and D_i are used to model onset and decay lag, respectively. (The number of such states is flexible; this example was chosen for illustration only.) The yearly loss to follow-up rate is l , and the yearly drop-out and drop-in rates are c and b , respectively. Note that $1 - \Sigma$ represents 1 minus the sum of the remainder of the column, and zeroes are represented as blank elements. This model allows for patients to continually switch from compliance to noncompliance. The model accounts for staggered entry by assuming patients are administratively censored according to the study's accrual pattern, and can accommodate a wide range of distributional assumptions, either parametric or nonparametric. Furthermore, event, loss, and noncompliance rates within subintervals can be obtained. Under a common set of assumptions, Lakatos's^[4] method approaches WFD as the number of subintervals increases.

Other sample size calculations based on the binomial distribution include Shuster^[5] (without adjustment for noncompliance) and Palta and McHugh^[6] (with adjustment for noncompliance).

SAMPLE SIZE CALCULATION FOR EXPONENTIAL MODEL

The simplest parametric survival model assumes that event times are exponentially distributed, which is equivalent to the assumption of constant hazard rates (designated by λ_e

and λ_c for the two groups). Sample size calculation can be based on the likelihood ratio test (exponential MLE test) for equality of hazards.

Schoenfeld and Richter^[7] used large-sample normal theory to generate nomograms to convert accrual and follow-up durations into the required sample size under the assumption of uniform entry. These nomograms can also be used (with iteration) to determine the accrual and follow-up durations for a fixed rate of entry. Two separate figures are given for 80% and 90% power; a more complicated nomogram can be used for any desired power and to find power as a function of the treatment difference.

Rubinstein et al.^[8] discussed sample size for the Mantel-Haenszel test. They assumed: (1) Poisson accrual over a period, T_a , and an additional follow-up period, T_f , and (2) loss to follow-up times independently and exponentially distributed with parameters, ϕ_e and ϕ_c . This resulted in the total sample size for a one-sided test of

$$N = \left(\frac{Z_\alpha + Z_\beta}{\ln(\theta)} \right)^2 \left[\frac{1}{E(P_e)} + \frac{1}{E(P_c)} \right] \quad (2)$$

where

$$E(P_j) = \left[\frac{1 - e^{-\lambda_j^* T_f} (1 - e^{-\lambda_j^* T_a})}{\lambda_j^* T_a} \right] \left(\frac{\lambda_j}{\lambda_j^*} \right) \quad (3)$$

θ is the hazard ratio, and $\lambda_j^* = \lambda_j + \phi_j$, $j = e, c$.

Assume that the minimal relevant difference is $|\lambda_e - \lambda_c|$, patients will be recruited at a uniform rate over an accrual period T_a , and T_f is an additional follow-up period after completion of recruitment. Then the total sample size for a one-sided test is given by Lachin^[9] as

$$N = \frac{(Z_\alpha \sqrt{\phi(\bar{\lambda})(Q_e^{-1} + Q_c^{-1})} + Z_\beta \sqrt{\phi(\lambda_e)Q_e^{-1} + \phi(\lambda_c)Q_c^{-1}})^2}{(\lambda_e - \lambda_c)^2} \quad (4)$$

where Q_e and Q_c are the proportions of patients in each group,

$$\bar{\lambda} = Q_e \lambda_e + Q_c \lambda_c \quad (5)$$

and

$$\phi(\lambda) = \lambda^2 \left[1 - \frac{e^{-\lambda T_f} - e^{-\lambda(T_a + T_f)}}{\lambda T_a} \right]^{-1} \quad (6)$$

Assuming the drop-out rate c , Lachin's^[9] formula for the effective value, p_e^* , of the T -year event rate, p_e , was

$$p_e^* = p_e(1 - c) + p_c c \quad (7)$$

so that the effective treatment difference is

$$\delta^* = p_e^* - p_c = (1 - c)(p_e - p_c) \quad (8)$$

Donner^[10] compared Lachin's method^[9] with Schork and Remington's^[12] and HRGE, and concluded that Lachin's^[9] is the most conservative because it characterizes drop-outs completely by the control group event rate.

Lachin and Foulkes^[11] extended Lachin's^[9] method to allow for nonuniform entry, loss to follow-up, noncompliance, and a stratified analysis. Considering nonuniform patient entry, they derived

$$\phi(\lambda) = \lambda^2 \left\{ 1 + \frac{\gamma e^{-\lambda(T_a + T_f)} [1 - e^{(\lambda - \gamma)T_a}]}{(1 - e^{-\gamma T_a})(\lambda - \gamma)} \right\}^{-1} \quad (9)$$

where γ is the parameter in a truncated exponential entry distribution. Sample size is then evaluated by substituting $\phi(\lambda)$ into Eq. 6. When losses to follow-up are considered,

$$\phi(\lambda, \eta) = \lambda^2 \left(\frac{\lambda}{\lambda + \eta} \left\{ 1 - \frac{e^{-(\lambda + \eta)T_f} - e^{-(\lambda + \eta)(T_a + T_f)}}{T_a(\lambda + \eta)} \right\} \right)^{-1} \quad (10)$$

where η is the loss to follow-up rate. The noncompliance adjustment simply and conservatively adjusts for the noncompliance rates:

$$N_w = \frac{N}{(1 - w_e - w_c)^2} \quad (11)$$

where N is the total sample size required with full compliance, and w_e and w_c are the noncompliance rates in the experimental and control groups, respectively.

Hwang and Chen^[12] extended Lachin and Foulkes's method^[11] to consider onset lag. Other sample size calculations based on exponential models include those of Pasternack and Gilbert,^[13] Pasternack,^[14] George and Desu,^[15] Bernstein and Lagakos,^[16] Makuch and Simon,^[17] and Taulbee and Symons,^[18] although none adjust for noncompliance.

SAMPLE SIZE CALCULATION FOR SEMIPARAMETRIC TEST

The logrank test is a commonly used procedure that does not assume a specific survival distribution but does assume proportional hazards, and has excellent power when that assumption is true. Gail^[19] suggested that a sample size method based on the logrank test be used if hazards are proportional, and that the binomial method be used if hazards are nonproportional and duration is comparable to mean survival. Assuming that the number of events at the i th event time is small relative to the number at risk, the true log-hazard ratio θ_R is small, and recruitment to each treatment group proceeds at a similar rate, then the required number of events is given by Collett^[20] as

$$d = \frac{4(Z_{\alpha/2} + Z_\beta)^2}{\theta_R^2} \quad (12)$$

The required total number of patients is found from

$$N = \frac{d}{P(\text{death})} = \frac{d}{1 - \frac{1}{6}\{\bar{S}(T_f) + 4\bar{S}(0.5T_a + T_f) + \bar{S}(T_a + T_f)\}} \quad (13)$$

where

$$\bar{S}(t) = \frac{S_c(t) + S_e(t)}{2} \quad (14)$$

and $S_c(t)$ and $S_e(t)$ are the estimated values of the survivor functions for individuals in the control and experimental groups, respectively, at time t .

Freedman^[21] provided a derivation of Lachin's^[9] method based on the asymptotic conditional expectation and variance of the logrank statistic, and published a set of tables of required sample sizes. The approach allowed arbitrary entry distributions but assumed that the expected event rate was well approximated by the event rate at the average follow-up. To calculate the sample size, instead of using $4/\theta_R^2$ as in formula 12, he suggested using $[(1 + \theta)/(1 - \theta)]^2$, where θ is the true hazard ratio. The total sample size can then be calculated as

$$N = \frac{2d}{p_e + p_c} \quad (15)$$

Freedman suggested accounting for staggered entry by using the values of p_e and p_c at a time equal to the average length of follow-up, and he proposed inflating the sample size by a factor of $1/(1-x)$, where x is the anticipated fraction lost to follow-up.

Similar to his 1986 method, in 1988 Lakatos^[22] derived the required sample size by using a discrete nonstationary Markov process that allows for stratification and time-dependent event rates, noncompliance, loss to follow-up, staggered entry, and onset and decay lag. This method calculates the expected value and variance of the logrank statistic using the ratios of the hazards and proportions at risk within each discrete interval. The required number of events can then be calculated as follows:

$$d = \frac{[Z_{\alpha/2}(\sum w_i^2 \rho_i \eta_i)^{1/2} + Z_\beta(\sum w_i^2 \rho_i \eta_i)^{1/2}]^2}{(\sum w_i \rho_i \gamma_i)^2} \quad (16)$$

where w_i is the i th Tarone–Ware weight (logrank is obtained if $w_i = 1$),^[23] $\rho_i = d_i / \sum d_i$ with d_i the number of events in the i th interval, $\eta_i = \phi_i / (1 + \phi_i)^2$ with ϕ_i the ratio of patients in the two treatment groups at risk in the i th interval, and $\gamma_i = [\phi_i \theta_i / (1 + \phi_i \theta_i)] - [\phi_i / (1 + \phi_i)]$ with θ_i the hazard ratio in the i th interval. The quantities ρ_i , η_i , and γ_i can be determined using the Markov model. The required total sample size is:

$$N = 2d / (p_e + p_c) \quad (17)$$

where p_e and p_c are the cumulative event rates.

Ahnn and Anderson^[24] extended Lakatos's^[22] formula to the case of testing the equality of K survival distributions using the Tarone–Ware class of statistics in the presence of time-dependent event rates and losses, noncompliance, staggered entry, and lag, and to the stratified logrank test.

Shih^[25] published a public domain SAS IML macro version of Lakatos's^[4,22] methods, called SIZE, which can be used to calculate sample size, power, and study duration. SIZE allows for nonproportional hazards, noncompliance, loss to follow-up, lag, and uncertainties in treatment benefit. HRGE, WFD, and Lakatos^[4,22] all considered linear lag functions; in contrast, SIZE uses a more flexible step function. In addition, SIZE considers the impact on power of uncertainties in the parameter values, which are expressed in terms of a discrete prior distribution. The sample size and power calculated using SIZE were found to be close to those using Lakatos's method.

Zucker and Lakatos^[26] described an analysis method accounting for onset lag, and presented two weighted logrank-type statistics designed to have good efficiency for various lags. They also pointed out that the sample size calculation should be specific to the future analysis method, something that can easily be accommodated by simulation-based methods.

Lakatos and Lan^[27] compared the approaches of Rubinstein et al.,^[8] Freedman,^[21] and Lakatos^[22] using simulations. Their conclusions were the following: (1) The formula-based methods of Rubinstein et al.^[8] and Freedman^[21] are attractive; however, because they are restrictive regarding the survival distributions and other time-dependent factors, the calculated sample sizes might not be accurate; (2) Lakatos's method^[22] has several advantages, including greater accuracy, adaptability to a broad range of conditions (noncompliance, staggered entry, loss to follow-up, and treatment lag), and ability to derive sample sizes for all statistics in the Tarone–Ware family and the G^p family of Harrington and Fleming.

Other sample size calculations based on semiparametric tests without adjustment for noncompliance include those of Palta and Amini,^[28] Yateman and Skene,^[29] Shuster,^[30] Schoenfeld,^[31,32] Hsieh and Lavori,^[33] Halpern and Brown,^[34] Cantor,^[35] Henderson et al.,^[36] Gail,^[37] and Lu and Pajak.^[38] Other sample size calculations with adjustment for noncompliance include Goldman and Hillman.^[39]

SAMPLE SIZE CALCULATION IN GROUP SEQUENTIAL TRIALS

Kim and Tsiatis^[40] proposed a group-sequential design utilizing the spending function described by Lan and DeMets.^[41] Although this method guarantees a desired significance level without requiring specification of the number and timing of

interim analyses in advance, design of the trial requires the number and timing of the interim analyses to be temporarily fixed. Kim and Tsiatis assumed exponential survival distributions, but their arguments extend naturally to the proportional hazards model after suitable transformation of the time scale. They did not account for competing risks or losses to follow-up apart from administrative censoring at the end of the study, and only considered one-sided tests and early termination for rejection of the null hypothesis.

Halpern and Brown^[42] extended their 1987 procedure^[34] for the logrank or Gehan test, incorporating group-sequential testing using either the Pocock^[43] or the O'Brien–Fleming^[44] boundary, and accounting for staggered entry. They presented a program implementing this method, called “mhghseq.” Gu and Lai^[45] expanded Halpern and Brown's^[42] approach; their method enables one to account for factors such as noncompliance, loss to follow-up, patient accrual patterns, and nonproportional hazards alternatives.

STATISTICAL SOFTWARE FOR SAMPLE SIZE CALCULATION

Dupont and Plummer^[46] developed a public domain computer program called POWER for studies with dichotomous, continuous, or time-to-event responses. POWER implements the Schoenfeld/Richter^[7] method for exponential survival distributions and uniform recruitment. As described above, Shih's^[25] public domain SAS IML macro implementation of Lakatos's^[4,22] methods, called SIZE, calculates sample size, power, or study duration. Natarajan et al.^[47] presented a computer program for use in the design of multiple-arm and factorial clinical trials.

Iwane et al.^[48] summarized and reviewed six commercial software packages for sample size and power calculations, although none account for noncompliance. They were:

1. Nsurv,^[49] based on Lachin and Foulkes's^[11] method.
2. Clinical Trials Design Program,^[50] based on Rubinstein et al.'s,^[8] Freedman's,^[21] and Zelen and Dannemiller's^[51] methods.
3. EGRET SIZ,^[52] based on Self et al.'s^[53] method.
4. POWER,^[46] based on Schoenfeld and Richter's^[7] method.
5. Power Analysis and Sample Size (PASS,^[54]), based on Lachin and Foulkes's^[11] method.
6. Ex-Sample,^[55] based on Schoenfeld and Richter's^[7] method.

The authors commented that differences in specifying the model make it difficult to compare across programs.

Lane^[56] gave an overview of several software packages for sample size, including nQuery Advisor,^[57] PASS,

Power and Precision, PS, Statistica Power Analysis, and STPlan, etc. Whitehead^[58] reviewed several software packages including EGRET SIZ, Nsurv, nQuery Advisor, PASS, Power and Precision, PS, Sampsize, Statistica Power Analysis, and STPlan (DSTPlan). Whitehead suggested choosing a software package based on data type; formulae; accuracy; quality of the output, tables, and graphs; and review articles.

nQuery Advisor is extensively used in many research settings and for many types of studies. For the logrank test sample size is based on Freedman^[21] and for test based on exponential survival sample size is based on Lakatos and Lan.^[27] Lane^[56] indicated that nQuery Advisor 4.0 has wide coverage, has a spreadsheet-like interface that is easy to use, and easily produces graphs of power vs. sample size, but customization options are limited.

Emerson^[59] reviewed two commercially available programs, EaSt version 2^[60] and PEST3 version 3 (Planning and Evaluation of Sequential Trials), which aid in the design and conduct of group-sequential trials. Emerson indicated that whereas the PEST3 version 3 provides greater flexibility than EaSt version 2, the use of either program can greatly increase the efficiency with which a clinical trialist plans and monitors a clinical trial.

CONCLUSION

This article described basic methodology and issues affecting sample size calculation for survival trials. Three basic approaches have been used, based on binomial proportions, exponential survival distributions, and tests based on semiparametric models. We reviewed the literature addressing the issues of staggered entry, loss to follow-up, onset and decay lag and noncompliance, and discussed related software/programs.

In survival trials, interest is not just in sample size—the design must consider the trade-offs among sample size, study duration, and event rate. Issues such as staggered entry, lag, and noncompliance can have a major impact on power and should be considered in the design. The choice of a model for sample size calculation should be in agreement with the planned analysis method. Methods based on the binomial model should be avoided when event rates are high. Methods proposed by Lachin and Foulkes^[11] are useful, but may not always have sufficient flexibility to account for all desired factors. Lakatos's^[22] Markov model gives great flexibility, but also places great demands on the user with respect to the number of parameters that must be specified. Because some features, such as the noncompliance rate and the lag function, might not be known with certainty, it may be best to explore the impact of these features on sample size in a sensitivity analysis.

Abstract

Sample size determination can be based on either the desired power of a particular statistical test for a population parameter or the desired precision of a confidence interval estimator of a population parameter when sampling from a large population. This entry reviews methods of determining sample sizes for statistical tests.

INTRODUCTION

Sample size determination refers to the evaluation of the sample size desired or required for a study during the design stage, before data are collected. A fundamental rule of sample size determination is that the method of evaluation should be based on the planned method of analysis. In sample size evaluation, one must strike a balance between enrolling sufficiently many patients to detect a clinically important difference and not wasting important resources.

Sample size determination can be based on either the desired power of a particular statistical test for a population parameter or the desired precision of a confidence interval estimator of a population parameter when sampling from a large population. A hypothesis test tells us whether the observed data are consistent with the null hypothesis; a confidence interval tells us which hypotheses are consistent with the observed data. Most of the literature on sample size determination discusses the power function of a statistical test rather than the precision of an estimator. However, it is well known that there is a simple correspondence between the two approaches.

OVERVIEW

Statistical tests can be conducted in many ways, but the setting most frequently encountered in clinical trials is comparative, in which two or more treatments are compared. In most cases, the null hypothesis, H_0 , is that the experimental treatment has no different effect on the outcome compared

with the control. When testing the experimental treatment, it may be assumed that one has introduced this new treatment because it is thought to be superior to the control, and the trial is being carried out to “prove” this. On the other hand, experimental treatments are also introduced that are equivalent (or noninferior) to the control, i.e., expected to have no better efficacy, or minimally poorer efficacy than control. Such a treatment may be introduced because this new treatment may have other benefits; for example, it is less toxic, less expensive, or easier to administer, takes less time to treat, or has fewer side effects. One key difference between testing for superiority and equivalence is that the former usually needs the specification of the smallest clinically meaningful and achievable treatment difference in the alternative hypothesis, H_a , while the latter requires the specification of the largest acceptable treatment difference in the null hypothesis, H_0 .

When conducting a statistical test, two types of error must be considered: Type I (false positive, i.e., rejecting the null hypothesis given that the null hypothesis is true) and Type II (false negative, i.e., failing to reject the null hypothesis given that the alternative hypothesis is true), with the probabilities, α and β , respectively. The power of a statistical test refers to the probability of rejecting the null hypothesis when the alternative is true, i.e., $1 - \beta$. Between the two types of error, the Type I error has traditionally been thought of as more critical. However, a smaller Type I error rate results in a lower power. On balance, primary importance is still given to the Type I error, and a properly higher sample size is needed to achieve higher power when both possible and necessary. In any statistical test, one assesses the probability of observing values as extreme or more extreme than the data observed under the null hypothesis, commonly termed the p value. Usually “the

The views expressed in this paper are those of the authors and not necessarily of the U.S. Food and Drug Administration.

data” are summarized in the form of an estimator or a sufficient statistic for an interesting parameter, termed a test statistic, and statistical significance is declared if the resulting p value is less than the preselected significance level, α .

In clinical trials, it is often the case that there are many interesting outcome or endpoint variables. In order to strike a balance between the desirability of assessing the effect of treatment on many variables and maintaining adequate power for specific variables, usually one primary variable is selected and used to determine the sample size. Otherwise, a multiple comparison adjustment is often applied to the sample size calculations through the significance levels assigned to the individual primary outcomes. The sample size is then chosen so that there is adequate power for each primary variable. While multiple comparisons are appropriate only if one will claim significance when any of the primary variables is significant, nominal significance level can be used to assure the significance for all of the primary variables.

Another critical factor in sample size calculation is the selection of the assumed parameters in the chosen population. The adequacy of the sample size determined depends on the accuracy of the initial specification of the parameters. For the purpose of planning a study, therefore, it is always advisable to consider a range of population parameters over which the planned analysis is conducted for a specific sample size.

Numerous articles and reference textbooks provide comprehensive reviews of sample size determination from the perspective of either the precision of an estimator or the power of a test. There is no one response to the general question of how many patients must be included in the treatment and the control groups. In general, sample size determination varies over the type of patient population (e.g., a single population vs. two populations), the type of response measurement (e.g., actual measurement vs. proportion successful), the type of statistical analysis (e.g., time-specific actuarial life table probability vs. crude probability), the type of study design (e.g., paired vs. independent or parallel vs. crossover), and other factors. The following is a compendium of exact and asymptotic formulas for estimating the sample size in clinical trials. Before the general formulas are reviewed, additional consideration is given to the factors that should be accounted for in sample size calculation.

SAMPLE SIZE ADJUSTMENT

A Simple Adjustment for the t -Test Statistic

If an estimator or a sufficient statistic of an interesting parameter is normally distributed, at least asymptotically, the sample size formula frequently takes the form

$$N_{\text{tot}} = \frac{c^2(z_{\alpha/2}\sigma_0 + z_\beta\sigma_1)^2}{\delta^2} \quad (1)$$

Here, N_{tot} is the total sample size for a two-sided test, c is a constant, z_α is the standard normal deviate with probability α of being exceeded, σ_0 and σ_1 are the standard deviations under the null and alternative hypotheses, respectively, and δ is the treatment effect. In one-sided test, $z_{\alpha/2}$ is replaced by z_α in Eq. 1.

If the test statistic has Student's t -distribution instead, then the use of Eq. 1 will underestimate the required sample size, although this effect is increasingly negligible for increasing degrees of freedom, df , of the t statistic. An adequate adjustment is obtained by the correction factor $f = (df + 3)/(df + 1)$, where the actual total sample size is fN and N is obtained from Eq. 1 (see Ref. [1]).

A Simple Adjustment for Missing Values

In some cases, part of the information in the data is missing completely at random (purely by chance). Then the sample size required should be adjusted upwards because the missing information would affect the power of a test and the precision of a confidence interval of a parameter. If M is the rate of missing information, then a simple adjustment is (see Ref. [2], p. 0000)

$$N_{\text{adj}} = \frac{N}{1 - M} \quad (2)$$

A Simple Adjustment for Unequal Allocation

It is well known that power is maximized and total sample size minimized for two equal-sized independent treatment groups if the population variances are equal. However, due to ethical considerations, unequal-sized groups may be desirable. Let subscripts “e” and “c” denote the experimental and control group, respectively. Suppose that the unequal sizes are reflected in the sample fractions, Q_e and Q_c , where $n_e = Q_e N$, $n_c = Q_c N$, $Q_e + Q_c = 1$, and $N = n_e + n_c$. Obviously, $Q_e = Q_c = 0.5$ is for the balanced case. An adjustment for the unbalanced case is

$$N_{\text{unbal}} = \frac{(Q_e^{-1} + Q_c^{-1})}{4} N_{\text{bal}} \quad (3)$$

where N_{bal} and N_{unbal} are the total sample size for balanced case and unbalanced case, respectively.^[2] That is, the unbalanced design requires $[(Q_e^{-1} + Q_c^{-1})/4 - 1]100\%$ larger sample size to provide the same level of power as the balanced design.

SAMPLE SIZE BASED ON MEANS

In this section, the outcome variable is continuous or quantitative. It is convenient to assume that the estimator or test statistic of an interesting parameter is normally distributed, at least asymptotically.

A Single Mean

In this case, there is no independent control group included in the clinical trials. The clinical decision is often based on the subjective evaluation of the outcome.

Hypothesis Test Approach

For the test $H_0: \mu = \mu_0$ with some a priori specified mean value μ_0 and variance σ_0^2 against an alternative $H_a: \mu = \mu_1 \neq \mu_0$ with variance σ_1^2 , the test statistic is

$$Z = \frac{\bar{Y} - \mu_0}{\sigma_0 / \sqrt{N}}$$

where $\bar{Y}$ is the mean of a single sample of observations. Then for specified α , β , μ_0 , μ_1 , σ_0 , and σ_1 , the total sample size required to ensure power $1 - \beta$ of detecting the difference $\delta = \mu_1 - \mu_0$ with a test at the significance level α is given by

$$N = \frac{(z_\alpha \sigma_0 + z_\beta \sigma_1)^2}{\delta^2} \quad (4)$$

In a clinical trial, σ_0 and σ_1 can be specified based on prior experiments using the same measurements or estimated from a small preliminary or “pilot” study. In these cases, it is best to use the largest value expected. If $\sigma_0 = \sigma_1 = \sigma$, Eq. 4 reduces to

$$N = \frac{\sigma^2 (z_\alpha + z_\beta)^2}{\delta^2} \quad (5)$$

Confidence Interval Approach

Suppose that one wishes to estimate the mean μ of a large population with variance component σ^2 using an estimator $\bar{Y}$ with variance σ^2/N . Then the sample size required to provide an interval estimator with the precision e at confidence level $1 - \alpha$ for a specified variance component σ^2 is given by

$$N = \left(\frac{z_{\alpha/2} \sigma}{e} \right)^2 \quad (6)$$

Correspondence of the Two Approaches

If $\sigma_0 = \sigma_1 = \sigma$, the N derived using a $1 - \alpha$ confidence interval to ensure a precision e is approximately the same as the N required to detect a difference $\mu_1 - \mu_0 = e$ with power 0.5 using a two-sided test. In this case, $e = z_{\alpha/2} \sigma / \sqrt{N}$. However, when $\sigma_0 \neq \sigma_1$, e is actually $z_{\alpha/2} \sigma_1 / \sqrt{N}$ because the variance under the alternative should be used to construct a confidence interval.^[2]

Two Independent Groups

In this case, two treatments are compared. Assume that the outcome variable has the means μ_1 and μ_2 , with the standard deviations σ_1 and σ_2 , respectively, for the two treatments. One wishes to estimate the difference of two population means to test for either superiority of one treatment to another or equivalence of the two treatments, in terms of the population mean.

Parallel Design

The simplest and probably most frequently employed design for a clinical trial is the parallel groups design. Eligible patients who have given their informed consent are randomly assigned to receive one and only one of two treatments.

Confidence Interval Approach Suppose that one wishes to estimate the difference of means, $\mu_1 - \mu_2$, with the common standard deviation $\sigma_1 = \sigma_2 = \sigma$. Based on normal theory, the sample size required to provide an interval estimate with the precision e at confidence level $1 - \alpha$ for a given variance component σ^2 is given by

$$N = \frac{2(z_{\alpha/2} \sigma)^2}{e^2} \quad (7)$$

This equation is for a two-sided confidence interval and is also applicable to the one-sided case by simply replacing $z_{\alpha/2}$ by z_α .

Hypothesis Test for Superiority Approach Consider the statistical model $Y_{ij} = \mu_i + e_{ij}$, $i = 1, 2$; $j = 1, 2, \dots, n$, where Y_{ij} denotes the measurement of outcome response on the j th subject for the i th treatment, μ_i is the underlying true mean response for the i th treatment, and e_{ij} 's denote the independently identically distributed measurement errors with common variance σ^2 . For the test $H_0: \mu_1 - \mu_2 = 0$ against an alternative $H_a: \mu_1 - \mu_2 \neq 0$ with common variance σ^2 , the test statistic is

$$Z = \frac{\bar{Y}_1 - \bar{Y}_2}{\sigma \sqrt{2/n}}$$

where $\bar{Y}_1$ and $\bar{Y}_2$ are the means of two independent samples and n is the sample size for each treatment group. Then, for specified α , β , $\delta = \mu_1 - \mu_2$, and σ^2 , the required sample size for each treatment group is

$$n = \frac{2\sigma^2 (z_{\alpha/2} + z_\beta)^2}{\delta^2} \quad (8)$$

and then the total sample size is $N = 2n$. For a one-sided test, the required sample size for each treatment group is obtained by substituting $z_{\alpha/2}$ by z_α in Eq. 8.

2 × 2 Crossover Design

The two-period crossover design consists of two treatments, which are conventionally labeled as A and B. Each subject (patient) receives the two treatments, with half the subjects randomly assigned to receive the treatments in the sequence AB and the rest in the sequence BA. Let $\bar{Y}_{ijk}$ be the measurement for the j th subject in the i th sequence of treatment at the k th period. Each of n patients in sequence 1 receives treatment A in period 1 and treatment B in period 2; each of n patients in sequence 2 receives the treatments in reverse order. If carryover effects are not present, an adequate model is

$$Y_{ijk} = \mu + \zeta_i + \xi_{ij} + \pi_k + \phi_l + e_{ijk} \quad (9)$$

$i = 1, 2$; $j = 1, 2, \dots, n$; $k = 1, 2$; $l = i - (-1)^i \delta_{2k}$; and $\delta_{2k} = 1$ if $k = 2$, $\delta_{2k} = 0$ otherwise. Here, μ is the overall mean; ζ_i the effect of the i th sequence; ξ_{ij} the effect of the j th patient within the i th sequence, which is the between-subject error; π_k the effect of the k th period; ϕ_l the effect of the l th treatment; and e_{ijk} the effect of the j th subject within the i th sequence at the k th period, which is the within-subject error. For the fixed source of variation, ζ_i , π_k , and ϕ_l , the standard constraints are assumed, i.e., the main effects sum to zero. For the random effects, ξ_{ij} and e_{ijk} , it is assumed that each set of error terms $\{\xi_{ij}\}$ and $\{e_{ijk}\}$ is independent and identically normally distributed with mean 0 and variance σ_s^2 and σ_e^2 , respectively, and the set of two error terms (ξ_{ij}, e_{ijk}) be independently distributed. The assumptions imply that the measurements have the same variance $\sigma_s^2 + \sigma_e^2$; the measurements on different subjects are independent; the measurements on the same subject within different treatment periods have covariance σ_s^2 .

For the test $H_0 : \phi_1 = \phi_2$ against an alternative $H_a : \phi_1 \neq \phi_2$, the difference of the measurements between periods 1 and 2 on each subject is considered by defining $d_{ij} = Y_{ij1} - Y_{ij2}$. Let $\phi_d = 2(\phi_1 - \phi_2)$ and $\hat{\phi}_d = \bar{d}_1 - \bar{d}_2$, then the estimator $\hat{\phi}_d$ is such that

$$E(\hat{\phi}_d) = \phi_d \text{ and } \text{Var}(\hat{\phi}_d) = \frac{2\sigma_d^2}{n^*} \quad (10)$$

Where $\sigma_d^2 = 2\sigma_e^2$ and n^* is the required number of subjects for each of the two sequences. Under the null hypothesis $\phi_1 = \phi_2$, and using the pooled estimator, $\hat{\sigma}_d^2$, of σ_d^2 , the test statistic

$$T_d = \frac{\hat{\phi}_d}{(\hat{\sigma}_d^2 / n^*)^{1/2}} \quad (11)$$

has Student's t -distribution with $2(n^* - 1)$ df . Note that for the two-period crossover design, the variance of the intra-subject differences (d_{ij}) is $2\sigma_e^2$ and the expected value of the difference between the two mean intrasubject differences $(\bar{d}_1 - \bar{d}_2)$ is $2(\phi_1 - \phi_2)$. Therefore, the required number of subjects for each of the two sequences is

$$n^* = \frac{2(2\sigma_e^2)(z_{\alpha/2} + z_\beta)^2}{[2(\phi_1 - \phi_2)]^2} = \frac{\sigma_e^2(z_{\alpha/2} + z_\beta)^2}{\delta^2} = \frac{n(1 - R)}{2} \quad (12)$$

where

$$n = \frac{2(\sigma_s^2 + \sigma_e^2)(z_{\alpha/2} + z_\beta)^2}{\delta^2} \quad (13)$$

would be the number of subjects required for each treatment group if the study were performed using two parallel groups, $\delta = \phi_1 - \phi_2$, and $R = \sigma_s^2 / (\sigma_s^2 + \sigma_e^2)$, the intraclass correlation coefficient. Even if R is as low as 0.5, the total number of subjects required for a two-period crossover study with a specified power is one quarter of the total number required for a parallel groups study with the same power. Because each subject is measured twice in a two-period crossover study, the total number of measurements on the $2n^*$ subjects in it is

$$2 \times 2n^* = 2n(1 - R) \quad (14)$$

a fraction $1 - R$ of the total of $2n$ measurements in the parallel groups study.^[3]

Parallel Design with Baseline and Repeated Measurements

Before randomization, repeated measurements can be used to identify patients who are eligible for the trial. In the long run, an outcome variable may be measured frequently to assure that the outcome is adequately controlled and accurate measurement is obtained. It also could be measured frequently to study the time course of response. Furthermore, because the variability of the measurement is a crucial factor for sample size, one can use repeated measurements to reduce the variability. For example, one can average all of the postrandomization measurements for an individual. In addition, it may reduce the study cost if enrolling more patients is not easy and more costly than taking repeated measurements on each patient for the desired power.

It is preferred to combine baseline (pretreatment) information with posttreatment assessment in the comparison of two treatments if the correlation between baseline and posttreatment is substantially large (usually greater than 0.5). Otherwise, only the posttreatment measurement is used.

Frison and Pocock^[4] explored the use of simple summary statistics for analyzing repeated measurements with baseline measurements in randomized clinical trials with two treatments and provided the methods for determining sample sizes in repeated measurements as follows.

Suppose a randomized clinical trial has two treatment groups with n_i patients per group, and all patients have p pretreatment visits, $m = -(p - 1), \dots, 0$ and r posttreatment visits, $m = 1, \dots, r$. A quantitative measurement is observed

at every visit for every patient, and the following simple model is considered:

$$\begin{aligned} Y_{ijm} &= \mu_{im} + e_{ijm} \\ i &= 1, 2; j = 1, 2, \dots, n_i; \\ m &= -(p-1), \dots, 0, 1, \dots, r \end{aligned} \quad (15)$$

Here, μ_{im} is the underlying true mean response for treatment i at time m . As a result of randomization, it is reasonable to assume $\mu_{1m}^{\text{pre}} = \mu_{2m}^{\text{pre}}$ for the pretreatment visits $m \leq 0$. e_{ijm} is the individual j th patient “error” or variation around the underlying mean μ_{im} , and these errors will not be independent within patients. For simplicity, compound symmetry structure over time points is assumed with equal variance σ^2 for all time points and both treatments and also equal correlation ρ between all pairs of time points on each patient. The correlation ρ is also expected to be substantial (typically greater than 0.5 in most trials) because it reflects the consistency of patient effects over time. Because in many clinical trials the primary objective is to assess the average response to treatment over time, often (but not necessarily) in anticipation that treatment response is liable to occur quickly and to remain reasonably steady over time, the following three possible methods of analysis are considered:

1. Posttreatment means: a simple analysis using the mean for each patient’s posttreatment measurements as the summary measure. For each individual, the summary statistic is

$$\bar{Y}_{ij.}^{\text{post}} = \frac{1}{r} \sum_{m=1}^r Y_{ijm} \quad (16)$$

Then, the overall posttreatment mean difference is

$$\frac{1}{n_1} \sum_{j=1}^{n_1} \bar{Y}_{1j.}^{\text{post}} - \frac{1}{n_2} \sum_{j=1}^{n_2} \bar{Y}_{2j.}^{\text{post}} = \bar{Y}_{1..}^{\text{post}} - \bar{Y}_{2..}^{\text{post}} \quad (17)$$

which has the expected value

$$\frac{1}{r} \sum_{m=1}^r (\mu_{1m} - \mu_{2m}) = \bar{\mu}_{1.}^{\text{post}} - \bar{\mu}_{2.}^{\text{post}} \quad (18)$$

2. Mean changes: a simple analysis of each patient’s difference between the mean of posttreatment measurements and the mean of baseline measurements, the latter often consisting of just a single baseline value per patient. For each individual, the summary statistic is mean change,

$$\frac{1}{r} \sum_{m=1}^r Y_{ijm} - \frac{1}{p} \sum_{m=-(p-1)}^0 Y_{ijm} = \bar{Y}_{ij.}^{\text{post}} - \bar{Y}_{ij.}^{\text{pre}} \quad (19)$$

Then the overall treatment difference in these mean changes is

$$\begin{aligned} \frac{1}{n_1} \sum_{j=1}^{n_1} (\bar{Y}_{1j.}^{\text{post}} - \bar{Y}_{1j.}^{\text{pre}}) - \frac{1}{n_2} \sum_{j=1}^{n_2} (\bar{Y}_{2j.}^{\text{post}} - \bar{Y}_{2j.}^{\text{pre}}) \\ = (\bar{Y}_{1..}^{\text{post}} - \bar{Y}_{1..}^{\text{pre}}) - (\bar{Y}_{2..}^{\text{post}} - \bar{Y}_{2..}^{\text{pre}}) \end{aligned} \quad (20)$$

which has expected value again equal to $\bar{\mu}_{1.}^{\text{post}} - \bar{\mu}_{2.}^{\text{post}}$, since the pretreatment expected values are the same for both treatments.

3. Analysis of covariance: between-patient variations in baseline measurements are taken into account by using the mean baseline measurement for each patient as a covariate in a linear model for treatment comparison of posttreatment means. The model is as follows:

$$\bar{Y}_{ij.}^{\text{post}} = \bar{\mu}_{i.}^{\text{post}} + \beta (\bar{Y}_{ij.}^{\text{pre}} - \bar{\mu}_{..}^{\text{pre}}) + \varepsilon_{ij} \quad (21)$$

where ε_{ij} ’s are independent random errors with assumed constant variance. With estimate $\hat{\beta}$ obtained by least squares and by defining

$$\bar{Y}_{ij.}^{\text{cov}} = \bar{Y}_{ij.}^{\text{post}} - \hat{\beta} (\bar{Y}_{ij.}^{\text{pre}} - \bar{Y}_{..}^{\text{pre}}) \quad (22)$$

the estimated mean treatment difference is

$$\frac{1}{n_1} \sum_{j=1}^{n_1} \bar{Y}_{1j.}^{\text{cov}} - \frac{1}{n_2} \sum_{j=1}^{n_2} \bar{Y}_{2j.}^{\text{cov}} = \bar{Y}_{1..}^{\text{cov}} - \bar{Y}_{2..}^{\text{cov}} \quad (23)$$

which again has expected value $\bar{\mu}_{1.}^{\text{post}} - \bar{\mu}_{2.}^{\text{post}}$.

It is convenient to assume that sample size is sufficiently large that the normal approximation to the t -distribution can be applied. For two equal sized treatment groups with null hypothesis $H_0: \bar{\mu}_{1.}^{\text{post}} = \bar{\mu}_{2.}^{\text{post}}$ and alternative $H_a: \bar{\mu}_{1.}^{\text{post}} \neq \bar{\mu}_{2.}^{\text{post}}$, the required sample size for each treatment group is approximately

$$n = \frac{2\sigma^2}{\delta^2} \left[\frac{1 + (r-1)\rho}{r} - \frac{p\rho^2}{1 + (p-1)\rho} \right] (z_{\alpha/2} + z_\beta)^2 \quad (24)$$

for the method of covariate analysis,

$$n = \frac{2\sigma^2}{\delta^2} \left[\frac{1 + (r-1)\rho}{r} \right] (z_{\alpha/2} + z_\beta)^2 \quad (25)$$

for the posttreatment means method, and

$$n = \frac{2\sigma^2}{\delta^2} \left[\frac{1 + (r-1)\rho}{r} - \frac{(p+1)\rho - 1}{p} \right] (z_{\alpha/2} + z_\beta)^2 \quad (26)$$

for the approach of mean changes, respectively, for given power $1 - \beta$, significance level α and detectable difference $\delta = \bar{\mu}_{1.}^{\text{post}} - \bar{\mu}_{2.}^{\text{post}}$. For the same power and when $\rho > 0.5$, the method of covariate analysis always requires a smaller number of patients.

Suppose only r posttreatment measurements are taken, a constant mean over time points for each treatment is expected, and the effect of time points and the interaction

of time point with treatment are not significant. Then the statistical model of Eq. 15 can be rewritten as

$$Y_{ijm} = \mu_i + f_j + e_{ijm} \quad i = 1, 2; \\ j = 1, 2, \dots, n; \quad m = 1, 2, \dots, r \quad (27)$$

where f_j denotes the effect of the j th subject with mean 0 and variance σ_s^2 , e_{ijm} 's denote the independently, identically distributed errors of measurement with mean 0 and common variance σ_e^2 , and these are uncorrelated. The assumptions imply compound symmetry structure over time points with equal variance $\sigma^2 = \sigma_s^2 + \sigma_e^2$ for all time points and both treatments and also equal correlation $\rho = \sigma_s^2 / (\sigma_s^2 + \sigma_e^2)$ between all pairs of time points for each subject.

Then, for the test $H_0: \mu_1 = \mu_2$ against alternative $H_a: \mu_1 \neq \mu_2$, Eq. 25 becomes (see Ref. [3])

$$n = \frac{2(\sigma_s^2 + \sigma_e^2 / r)(z_{\alpha/2} + z_\beta)^2}{\delta^2} \quad (28)$$

Appealing to a quasi-score test statistic for a generalized linear model based on the generalized estimating equation (GEE) method, Liu and Liang^[5] presented a method to compute sample size for studies involving correlated observations. The case of repeated measurements discussed earlier is an example of correlated data. Because of the potential association for observations within a subject, the intrasubject correlation should be taken into consideration in both the design and the analysis stages. Common choices for correlation structure over repeated measurements include uncorrelated structure, compound symmetry structure, autoregressive structure, and unstructured correlation. The first three correlation structures may be used for sample size calculations in most practical situations. There are no explicit sample size formulas for a generalized linear model, and numerical methods are required. However, for a typical two-sample problem with repeated measurements and compound symmetry correlation structure, an explicit formula for the required total sample size is available:

$$N = \frac{\sigma^2}{\pi_1 \pi_2 \delta^2} \left[\frac{1 + (r-1)\rho}{r} \right] (z_{\alpha/2} + z_\beta)^2 \quad (29)$$

where π_1 and π_2 are proportions of patients in the two treatment groups, respectively. Note that for the equal-sized case, i.e., $\pi_1 = \pi_2 = 0.5$, Eq. 29 is the same as Eq. 25.

2 × 2 Crossover Design with Repeated Measurements

Yue and Roach^[6] considered the extension of the model Eq. 9 for a 2 × 2 repeated measurements crossover design with mean summary:

$$Y_{ijkm} = \mu + \zeta_i + \xi_{ij} + \pi_k + \phi_l + e_{ijk} + \tau_m + (\zeta\tau)_{im} \\ + \omega_{ijm} + (\pi\tau)_{km} + (\phi\tau)_{lm} + f_{ijkm} \quad (30)$$

$i = 1, 2; j = 1, 2, \dots, n; k = 1, 2; l = i - (-1)^i \delta_{2k}; \delta_{2k} = 1$ if $k = 2, \delta_{2k} = 0$ otherwise; and $m = 1, 2, \dots, r$. In addition to the notation and assumptions in the model Eq. 9, τ_m is the effect of the m th time, $(\zeta\tau)_{im}$ the interaction effect of the m th time with the i th sequence, ω_{ijm} the effect of the j th subject within the i th sequence at the m th time, $(\pi\tau)_{km}$ the interaction effect of the m th time with the k th period, $(\phi\tau)_{lm}$ the interaction effect of the m th time with the l th treatment, and f_{ijkm} the random fluctuation of the j th subject within the i th sequence at the k th period and m th time.

For the fixed sources of variation, $\tau_m, (\zeta\tau)_{im}, (\pi\tau)_{km}$, and $(\phi\tau)_{lm}$, the main effect τ_m sums to zero, and the interaction effects sum to zero over both the r levels of time and the two levels of the main effect. For simplicity, it is assumed that each set of $\{\omega_{ijm}\}$ and $\{f_{ijkm}\}$ is independently and identically normally distributed with mean zero and variances σ_ω^2 and σ_f^2 , respectively, and the set of four error terms $(\xi_{ij}, e_{ijk}, \omega_{ijm}, f_{ijkm})$ be independently distributed. The assumptions imply compound symmetry structure over time points within each treatment period, i.e., equal variances for all time points and both treatments and also equal correlation between all pairs of time points. They also imply that the measurements have the same variance $\sigma_s^2 + \sigma_e^2 + \sigma_\omega^2 + \sigma_f^2$; the measurements on different subjects are independent; the measurements on the same subject within the same treatment period but at different time points have covariance $\sigma_s^2 + \sigma_e^2$; and the measurements on the same subject within different treatment periods have covariance $\sigma_s^2 + \sigma_\omega^2$ if at the same time point and σ_s^2 if at different time points.

Similarly, define

$$\phi_d = 2(\phi_1 - \phi_2) \\ \sigma_d^2 = 2(\sigma_e^2 + \sigma_f^2 / r) \\ \hat{\phi}_d = \bar{d}_{1..} - \bar{d}_{2..} \quad (31)$$

Then, using the similar t -test statistic, the required number of subjects for each of the two sequences for given power $1 - \beta$, significance level α , and detectable difference $\delta = (\phi_1 - \phi_2)$ with respect to Y_{ijkm} is approximately

$$n^* = \frac{(\sigma_e^2 + \sigma_f^2 / r)(z_{\alpha/2} + z_\beta)^2}{\delta^2} \quad (32)$$

If $r = 1$ (that is, there is no repeated measurement within each treatment period), then the model in Eq. 30 reduces to the model in Eq. 9, and n^* in Eq. 32 becomes n^* in Eq. 12.

If the interaction effects of the time with other factors and the main effect of the time are not significant, the model Eq. 30 can be simplified to

$$Y_{ijkm} = \mu + \zeta_i + \xi_{ij} + \pi_k + \phi_l + e_{ijk} + f_{ijkm} \quad (33)$$

where f_{ijkm} can be regarded as subsampling error. However, Eq. 32 is still valid for model Eq. 33.

Noninferiority Trials

In noninferiority (i.e., one-sided equivalence) trials, an objective is to show that an experimental treatment is as effective as a standard treatment (an active control) with respect to appropriate primary endpoint(s), from which it is then inferred that the experimental treatment is effective. In fact, in the comparison of the experiment to the standard treatment, it is really showing inferiority of no more than a prespecified noninferiority margin, delta, with respect to parameter(s) of interest, so that it is really “not-too-much-inferior.” The margin delta is the allowable reduction in therapeutic response and chosen based on the historical evidence of the effectiveness of the standard treatment and other clinical and statistical considerations relevant to the experimental treatment and the current study. The trials may be justified when considering the experimental treatment that is thought to be as effective, but perhaps not more effective than the standard. The experimental treatment may be preferred due to some reason other than effectiveness, in curing illness. However, a crucial issue for the noninferiority trials is agreement upon how much expense of reduced efficacy could be accepted as necessary for other benefits, such as reduced toxicity.^[7–10]

A sample size formula for this situation is

$$N_{\text{tot}} = \frac{c^2(z_\alpha\sigma_0 + z_\beta\sigma_1)^2}{(\delta - \delta_0)^2} \quad (34)$$

Here c is a constant, δ is the noninferiority margin, and δ_0 is the expected or true treatment difference. For noninferiority, one usually sets $\delta_0 = 0$. Eq. 34 is valid for confidence interval approaches.^[7]

For simplicity, it is assumed that higher means are more desirable, and μ_e and μ_s denote experimental and standard treatment means, respectively. For the hypothesis $H_0: \mu_s - \mu_e \geq \delta$ against alternative hypothesis $H_a: \mu_s - \mu_e < \delta$, where $\delta > 0$, the required sample size for each treatment group is

$$n = \frac{2\sigma^2(z_\alpha + z_\beta)^2}{(\delta - \delta_0)^2} \quad (35)$$

for given significance level α , power $1 - \beta$, common variance σ^2 , true mean difference $\delta_0 = \mu_s - \mu_e$, and sufficiently small difference δ that the two treatments are considered equivalent for practical purposes if $\delta_0 < \delta$.

Eq. 35 can be developed in terms of a one-sided $100(1 - \alpha)\%$ confidence interval for the difference $\mu_s - \mu_e$, with a specified probability $1 - \beta$ that the interval will not include a difference δ .

Paired Observations

In the case that the measurements in the two groups are linked together by pairing or repeated measures at

times a and b on the same patient, the t -test is conducted using the mean difference $\bar{d} = \bar{Y}_b - \bar{Y}_a$, with variance $\Sigma^2 = \sigma_d^2/n$, where $\sigma_d^2 = 2\sigma^2(1 - \rho)$ if $\sigma_a^2 = \sigma_b^2 = \sigma^2$, ρ being the correlation between the paired measurements. For the hypothesis $H_0: \mu_a - \mu_b = 0$ against an alternative $H_a: \mu_a - \mu_b = \delta \neq 0$, where δ is a clinically significant pre-specified value, the required number of sample pairs is approximately

$$n = \frac{\sigma_d^2(z_\alpha + z_\beta)^2}{\delta^2} \quad (36)$$

Here, σ_d^2 can be obtained from prior experience or estimated from a previous pilot study. Note that pairing is efficient only if $\rho > 0$, i.e., if there is positive correlation between the paired measurements. If no estimate of ρ is available, it is safe to assume $\rho = 0$ or, nominally, $\rho = 0.10$.^[11]

Note that Eq. 36 is applicable for an alternative $H_a: \mu_a - \mu_b \neq 0$ with $z_{\alpha/2}$ substituted for z_α and a detectable difference δ .

SAMPLE SIZE BASED ON PROPORTIONS

When the outcome measure in a clinical trial is a dichotomous variable, such as success versus failure, the data are usually expressed as a proportion of “success” p . The probability distribution of such a proportion is the binomial distribution $B(\pi, N)$ with parameters π (the true population proportion) and N (sample size). For large N , the binomial distribution asymptotically approaches a normal distribution $N(\mu, \sigma^2)$ with mean $\mu = \pi$ and variance $\sigma^2 = \pi(1 - \pi)/N$. In this case, the basic equations of tests for means may be employed as the approximate equations of tests for proportions.

A Single Proportion

Hypothesis Test Approach

For the one treatment group problem involving a single proportion, the hypothesis $H_0: \pi = \pi_0$ is tested to detect a clinically relevant alternative hypothesis $H_a: \pi = \pi_1$ where either $\pi_1 > \pi_0$ or $\pi_1 < \pi_0$. Based on a proportion p and large sample size N , the test statistic is $Z = (p - \pi)/\sigma_0$, where $Z \sim N(0, 1)$ and $\sigma_0 = \pi_0(1 - \pi_0)/N$, if H_0 is true. For the given significance level α and power $1 - \beta$, the equation for sample size N is (see Ref. [1])

$$N = \left[\frac{Z_\alpha \sqrt{\pi_0(1 - \pi_0)} + Z_\beta \sqrt{\pi_1(1 - \pi_1)}}{\pi_1 - \pi_0} \right]^2 \quad (37)$$

McNemar's χ^2 Test of Equality of Paired Proportions

When two groups of observation are linked together in a way such that matching on the sample individuals at

categories A and B. The basic data can be expressed as where m_{-+} , for instance, is the number of pairs with (−) for observation A and (+) for observation B, m_A and m_B are the total numbers for the observations A and B, respectively. Thus, the proportions (p 's)

		B		
		+	−	
A	+	m_{++}	m_{+-}	m_A
	−	m_{-+}	m_{--}	
		m_B		N

are defined as the ratios of frequencies (m 's) to the total number of pairs, N .

Analogous to the problem of t -tests for paired means, the null hypothesis for testing paired proportions is $H_0: \mu_d = (\pi_A - \pi_B) = 0$. Because the difference between π_A and π_B equals $(\pi_{++} - \pi_{--})$, the question can be expressed in terms of the discordant proportions π_{-+} and π_{+-} . This means that the hypothesis may be expressed as $H_0: \pi_{-+} = \pi_{+-} = \pi$. The test statistic for hypothesis H_0 is

$$Z = \frac{(p_{-+} - p_{+-})}{s}$$

where $s^2 = 2\bar{p}/N$ is the estimate of variance; $\bar{p} = (p_{-+} + p_{+-})/2$ is the estimate of π ; and $Z \sim N(0, 1)$ if H_0 is true. Note that Z^2 is equivalent to McNemar's χ^2 statistic usually used; thus, for given a significance level α and a power $1 - \beta$, the equation for sample size N is expressed as (see Ref. [1])

$$N = \left[\frac{Z_{\alpha/2} \sqrt{2\bar{\pi}} + Z_{\beta} \sqrt{\frac{2\pi_{-+}\pi_{+-}}{\bar{\pi}}}}{\pi_{-+} - \pi_{+-}} \right]^2 \quad (38)$$

where $\bar{\pi} = (\pi_{-+} + \pi_{+-})/2$.

Two Independent Proportions

Asymptotically Normal Method

A common clinical design is to employ two treatment groups in sample sizes n_1 , n_2 , and $n_2 = kn_1$ where k is the ratio of two sample sizes. For the null hypothesis $H_0: \pi_1 - \pi_2 = 0$, the exact sample size n_1 is determined by

$$n_1 = \min \left\{ n_1 : \prod (\pi_1, \pi_2 > 1 - \beta) \right\} \quad (39)$$

where

$$\prod (\pi_1, \pi_2) = \sum_{(x,y) \in C} \binom{n_1}{x} \binom{kn_1}{y} \pi_1^x (1 - \pi_1)^{n_1 - x} \pi_2^y (1 - \pi_2)^{kn_1 - y}$$

with the domain

$$C = \left\{ (x, y) : \frac{\sqrt{n_1 |\pi_1 - \pi_2|}}{\sqrt{\pi_1(1 - \pi_1) + \pi_2(1 - \pi_2)/k}} > Z_{\alpha} \right\}$$

and the critical value (see equation below)

With asymptotic normality assumption, the sample sizes n_1 and n_2 are expressed as

$$n_1 = \left[\frac{Z_{\alpha/2} \sqrt{\bar{\pi}(1 - \bar{\pi}) \left(1 + \frac{1}{k}\right)} + Z_{\beta} \sqrt{\pi_1(1 - \pi_1) + \frac{\pi_2(1 - \pi_2)}{k}}}{\pi_1 - \pi_2} \right]^2 \quad (40)$$

$$n_2 = kn_1$$

where $\bar{\pi} = (\pi_1 + k\pi_2)/(1 + k)$. For the equal sample size designs ($k = 1$), Eq. 40 becomes

$$n_1 = n_2 = \left[\frac{Z_{\alpha/2} \sqrt{2\bar{\pi}(1 - \bar{\pi})} + Z_{\beta} \sqrt{\pi_1(1 - \pi_1) + \pi_2(1 - \pi_2)}}{\pi_1 - \pi_2} \right]^2 \quad (41)$$

where $\bar{\pi} = (\pi_1 + \pi_2)/2$. Note that Eqs. 40 and 41 are without any continuity correction (see Ref. [11]).

Continuity Correction χ^2 Test

Based on Pearson χ^2 statistic and Yates's continuity correction, a formula for sample size calculation is given as

$$n_1 = \frac{n_1^*}{4} \left[1 + \sqrt{1 + \frac{(k+1)|\pi_1 - \pi_2|}{k(Z_{\alpha/2} + Z_{\beta})^2 \bar{\pi}(1 - \bar{\pi})}} \right]^2 \quad (42)$$

$$n_2 = kn_1$$

where n_1^* is determined by Eq. 40. For the equal sample size designs, Eq. 42 is

$$n_1 = \frac{n_1^*}{4} \left[1 + \sqrt{1 + \frac{2|\pi_1 - \pi_2|}{(Z_{\alpha/2} + Z_{\beta})^2 \bar{\pi}(1 - \bar{\pi})}} \right]^2 \quad (43)$$

where n^* is determined by Eq. 41 (see Ref. [12]).

Continuity-Corrected χ^2 Test (Fisher's Exact)

An improved equation for Fisher's exact test is given as

$$n_1 = \frac{n_1^*}{4} \left[1 + \sqrt{1 + \frac{2(k+1)}{kn_1^* |\pi_1 - \pi_2|}} \right]^2 \quad (44)$$

$$n_2 = kn_1$$

where n_1^* is determined by Eq. 40. For the equal sample size designs, Eq. 44 becomes

$$n = \frac{n^*}{4} \left[1 + \sqrt{1 + \frac{4}{n^* |\pi_1 - \pi_2|}} \right]^2 \quad (45)$$

where n^* is determined by formula Eq. 41 (see Ref. [12]).

Test for Relative Risk

In some cases of clinical trials, an estimate of anticipated event rate among the control group patients, π_c , has been estimated from past experience. One may then want to estimate the anticipated event rate of the experiment group, π_e , by relative risk

$$R = \frac{\pi_e}{\pi_c} \quad (46)$$

$$Z_u^* = \inf \left\{ Z_u : \sup \left\{ \sum_{(x,y) \in C} \binom{n_1}{x} \binom{kn_1}{y} \pi^{x+y} (1-\pi)^{(1+k)n_1 - (x+y)} \right\} \leq \alpha \right\}$$

instead of risk difference. In this case the null hypothesis is $H_0: R = 1$. The sample size of each group in an equal size design is determined by

$$n = \left\lceil \frac{Z_{\alpha/2} \sqrt{2\pi_R(1-\pi_R)} + Z_\beta \sqrt{\pi_c(1+R-\pi_c(1+R^2))}}{\pi_c(1-R)} \right\rceil^2 \quad (47)$$

where $\pi_R = \pi_c(1+R)/2$. Note that Eq. 47 is algebraically equivalent to Eq. 41. For the use of continuity correction, Eq. 47 is adjusted by adding $2/\pi_c |1-R|$ to the calculated value of sample size from Eq. 47 (see Ref. [13]).

Equivalence Approach

A question sometimes addressed in clinical trials is whether a new therapy is as effective as a standard therapy. Although it may be as effective or as nearly effective as the standard, the new therapy may provide some other meaningful advantages, such as being less expensive or less toxic than the standard therapy. Unlike the traditional concepts detecting the significant difference between two treatments, the statistical issue here is to test the equivalence. The therapies are considered equivalent for practical purpose if the difference is less than a given small value δ (assume that a larger proportion is more desirable and $\delta > 0$), i.e., if $\pi_s - \pi_e < \delta$. The null hypothesis and alternative hypothesis are $H_0: \pi_s \geq \pi_e + \delta$, $H_a: \pi_s < \pi_e + \delta$. The statistic for testing the null hypothesis is

$$z = \frac{p_s - p_e - \delta}{\sigma} \quad (48)$$

where

$$\sigma = \sqrt{\frac{p_s(1-p_s)}{n_s} + \frac{p_e(1-p_e)}{n_e}}$$

Therefore, one should set the sample sizes sufficiently large so that the confidence interval will not exceed some specified value δ with a desired power $1 - \beta$. This means that

$$\Pr \left(\frac{(p_s - p_e) - (\pi_s - \pi_e)}{\sigma} > \frac{\delta - (\pi_s - \pi_e)}{\sigma} - Z_\alpha \right) = \beta \quad (49)$$

For an equal-sample-size design, the sample size in each group is determined by (see Ref. [8])

$$n = \left\lceil \frac{\left(\frac{Z_\alpha + Z_\beta}{\pi_s - \pi_e - \delta} \right) \sqrt{\pi_s(1-\pi_s) + \pi_e(1-\pi_e)}}{1} \right\rceil^2 \quad (50)$$

More Than Two Independent Proportions

Test for Ordinal Data

When the patient response in two treatment groups is measured on an ordered categorical scale such as very good, good, moderate, poor, the data can be analyzed using techniques of logistic regression. Under the assumption of proportional odds, a formula for total sample size is

$$N = n_e + n_c = \frac{3(A+1)^2 (Z_{\alpha/2} + Z_\beta)^2}{A\theta_R^2 \left(1 - \sum_{i=1}^k \bar{\pi}_i^3 \right)} \quad (51)$$

where

n_e and n_c are the sample sizes for the experimental group and control group, respectively; A is the allocation ratio, $n_e = An_c$;

$\bar{\pi}_i$ is referred to as the anticipated proportion for category C_i ,

$$\bar{\pi}_i = \frac{(\pi_{ie} + \pi_{ic})}{2} \quad i = 1, 2, \dots, k \quad (52)$$

θ_R denotes the reference improvement, a point estimate of log-odds-ratio of the outcome C_i or better for an experimental subject relative to a control subject:

$$\theta_i = \log \left\{ \frac{Q_{ie}(1-Q_{ic})}{Q_{ic}(1-Q_{ie})} \right\} \quad (53)$$

$$Q_{iG} = \sum_{j=1}^i \pi_{jG} \quad G = e, c; \quad i = 1, 2, \dots, k-1$$

The sample size determination is illustrated as the follows. In most cases of clinical trials, the category probabilities in the control group π_{ic} have been estimated from past studies. Based on the previous experience, the

reference improvement θ_R has been also estimated in any given circumstance. Since the definition

$$\theta_i = \log \left\{ \frac{Q_{ie}(1-Q_{ic})}{Q_{ic}(1-Q_{ie})} \right\}$$

is true for all $i = 1, 2, \dots, k-1$, the cumulative probabilities of improvement Q_{ieR} in the experimental group can be anticipated

$$Q_{ieR} = \frac{Q_{ic}}{Q_{ic} + (1-Q_{ic})e^{-\theta_R}} \quad i = 1, 2, \dots, k-1 \quad (54)$$

That gives the category probabilities in the experimental group π_{ie} and the anticipated proportion $\bar{\pi}_i$, $i = 1, 2, \dots, k$. Then the sample size can be determined from Eq. 51 for the given significance level α , power $1-\beta$, and allocation ratio A (see Ref. [14]).

Test for Linear Trend in $G \times 2$ Tables

Let y_i be k mutually independent binomial variates based on sample sizes of n_i at dose level d_i and Y , U , and N be the relevant summations

$$Y = \sum_i y_i, \quad U = \sum_i y_i d_i, \quad N = \sum_i n_i, \quad i = 0, 1, \dots, k-1$$

Define $p = Y/N$, $q = 1 - p$, and $\bar{d} = \sum_i n_i d_i / N$. Assuming that the probability of response follows a linear trend on the logistic scale, $p_i = \exp(\gamma + \lambda d_i) / (1 + \exp(\gamma + \lambda d_i))$, an approximate test with continuity correction asymptotically approaches the normal distribution; that is,

$$z = \frac{U' - \Delta/2}{\sqrt{\text{var}(U'|Y)_{H_0}}} \sim N(0,1) \quad (55)$$

Where

$$U' = U - E(U|Y)_{H_0} = \sum_i y_i (d_i - \bar{d})$$

$$\text{var}(U'|Y)_{H_0} = pq \sum_i n_i (d_i - \bar{d})^2$$

and $\Delta/2$ is the continuity correction. When the Type I and Type II error probabilities are given by α and β , respectively, the following equation can be obtained:

$$E(U') - \frac{\Delta}{2} = Z_\alpha \sqrt{\text{var}(U')_{H_0}} + Z_\beta \sqrt{\text{var}(U')} \quad (56)$$

where

$$E(U') = \sum_i n_i p_i (d_i - \bar{d})$$

$$\text{var}(U')_{H_0} = pq \sum_i n_i (d_i - \bar{d})^2$$

$$p = \frac{\sum_i n_i p_i}{N}$$

and

$$\text{var}(U') = \sum_i n_i p_i q_i (d_i - \bar{d})^2$$

Let $r_i = n_i/n_0$ be the ratio of sample sizes of the i th group to that of the control group ($i = 0, 1, 2, \dots, k-1$) that may be determined in advance. Thus, sample size determination is focused on how to estimate the sample size of the control group. The sample size n_i of the i th group can be calculated directly via the ratio $r_i = n_i/n_0$ whenever n_0 is obtained. The sample size of the control group n_0 can be solved from the following quadratic equation with respect to $\sqrt{n_0}$:

$$n_0 = \left(\frac{n_0^*}{4} \right) \left[1 + \sqrt{1 + \frac{2\Delta}{n_0^* \sum_i \gamma_i p_i (d_i - \bar{d})}} \right]^2 \quad (57)$$

where n_0^* is the sample size of the control group without continuity correction (i.e., $\Delta = 0$) and is given as

$$n_0^* = \frac{\left[Z_\alpha \sqrt{pq \sum_i \gamma_i (d_i - \bar{d})^2} + Z_\beta \sqrt{\sum_i \gamma_i p_i q_i (d_i - \bar{d})^2} \right]^2}{\left[\sum_i \gamma_i p_i q_i (d_i - \bar{d}) \right]^2} \quad (58)$$

For the equal-sample-size design with $d_i = i$, for $i = 0, 1, 2, \dots, k-1$, the sample size per group is approximately expressed as (see Ref. [15])

$$n = \left(\frac{n^*}{4} \right) \left[1 + \sqrt{1 + \frac{2}{n^* \sum_i [i - 0.5(k-1)] p_i}} \right]^2 \quad (59)$$

where

$$n^* = \frac{\left[Z_\alpha \sqrt{\frac{k(k^2-1)pq}{12}} + Z_\beta \sqrt{\sum_i [i - 0.5(k-1)]^2 p_i q_i} \right]^2}{\left[\sum_i [i - 0.5(k-1)] p_i \right]^2} \quad (60)$$

SAMPLE SIZE IN SURVIVAL ANALYSIS

Survival analysis methods are designed for studies in which patients are followed until any event of interest occurs (e.g., death, heart attack, etc.), the patients are censored, or

the study ends. If the survival proportions of patients are simply compared, or all patients are followed for the same fixed time period, the sample size can be determined by the methods related to comparison of proportions. However, most survival studies are designed for comparing treatment groups on mean survival times rather than survival rates. For this reason, the sample size determinations for survival studies are differently considered from those for means or proportions. Similar to the methods for means and proportions, the sample size calculations for survival studies are derived under certain assumptions: proportional-hazard assumption or distribution assumption.

Log-Rank Test for Equality of Survival Curves

Schoenfeld^[16] and Freedman^[17] derived similar sample size formulas for the total number of events needed to be observed and the total number of patients per group needed to be recruited. Suppose that there are two groups of individuals, the experimental group and the control group. Assuming a proportional-hazards model for the survival times, the hazard event at time t for an individual in the experimental group, $h_e(t)$, can be expressed as

$$h_e(t) = \psi h_c(t) \quad (61)$$

where $h_c(t)$ is the hazard function at t for an individual in the control group and ψ is the unknown hazard ratio. Let θ , $\theta \in \Theta$, be the log-hazard ratio, $\theta = \log \psi$, then a zero value of θ indicates no treatment difference; negative value of θ means that survival is longer on the new treatment, and positive value of θ means that survival is longer on the standard treatment.

The required number of events is calculated in such a case to reject the null hypothesis that the observed value of θ is equal to zero at a significance level of α and with the desired power of $1 - \beta$. Both α and β are given for any design of survival study. The required number of events, d , can be calculated using

$$d = \frac{4(z_{\alpha/2} + z_{\beta})^2}{\theta^2} \quad (62)$$

where $z_{\alpha/2}$ and z_{β} are the upper $\alpha/2$ and the upper β points of the standard normal distribution, and θ is an estimate of Θ that might be chosen on the basis of the increase in median survival time, or other estimating method in the survival study. Freedman^[17] suggested using $\left[\frac{1 + e^{\theta}}{1 - e^{\theta}} \right]^2$ instead of $4/\theta^2$ for more accurate sample size. When θ is small, however, the results of these two methods are very close because

$$\left(\frac{1 + e^{\theta}}{1 - e^{\theta}} \right)^2 \approx \left(\frac{2 + \theta}{\theta + \theta^2/2} \right)^2 = \frac{4}{\theta^2} \quad (63)$$

The calculation of Eq. 62 assumes that an equal number of individuals is to be assigned to each treatment group. In the case of unequal sizes, for example, π_c and $(1 - \pi_c)$ as the proportion of individuals in the control and experimental groups, respectively, the required total number of events becomes

$$d = \frac{(z_{\alpha/2} + z_{\beta})^2}{\pi_c(1 - \pi_c)\theta^2} \quad (64)$$

An imbalance in number of individuals in the two groups will increase the total number of events required.

If the study has to be continued until a given percentage of the patients has had the events of interest, p , the total number of patients can be simply calculated

$$N = \frac{d}{p} \quad (65)$$

Otherwise, the probability of event over the duration of study needs to be taken instead of simple percentage p . Typically, individuals are recruited over an accrual period T_a . After recruitment is finished, there is an additional follow-up period T_f . The probability of an event over the duration of study can be calculated as

$$\begin{aligned} \text{Pr(event)} &= 1 - \frac{1}{6} \\ &\times \left[\bar{S}(T_f) + 4\bar{S}(0.5T_a + T_f) + \bar{S}(T_a + T_f) \right] \end{aligned} \quad (66)$$

where

$$\bar{S} = \frac{S_e(t) + S_c(t)}{2} \quad (67)$$

is the average survival function and $S_e(t)$ and $S_c(t)$ are the Kaplan–Meier estimate values of the survival functions for individuals on the experimental and control groups, respectively, at time t . Notice that there is no distribution assumption in Eqs. 66 and 67. Assuming that survival times are exponentially distributed, the average survival function is given by

$$\bar{S} = \frac{e^{-\lambda_e t} + e^{-\lambda_c t}}{2} \quad (68)$$

where estimates λ_e and λ_c can be estimated by means of the corresponding median survival times t_m (see Ref. [18]):

$$\lambda = \frac{\log 2}{t_m} \quad (69)$$

A variant on Eq. 69 for accrual and follow-up periods is given by Schoenfeld and Richter,^[19] who developed nomograms for calculating sample size. The nomograms are valid when survival is exponential and patients enter the study uniformly.

In the general case, Lakatos^[20] derived a method of sample size calculation by using a discrete nonstationary Markov process that allows any pattern of survival, non-compliance, loss to follow-up, drop-in, and lag in the effectiveness of treatment during the study period.

Test Based on Exponential Survival

Rubinstein et al.^[21] considered sample size estimation by assuming exponentially distributed survival duration. Their assumptions include that: (1) patients are accrued during the interval $[0, T]$ according to Poisson process and total trial length is $T + \tau$; (2) time from entry to event are independently and exponentially distributed in each of experimental and control groups, with parameters λ_e and λ_c , respectively; and (3) the losses to follow-up times are also independently and exponentially distributed in each group with parameters ϕ_e and ϕ_c , respectively. Based on the exponential maximum likelihood test, the sample size formula is given as

$$n = \left(\frac{z_\alpha + z_\beta}{\ln(\theta)} \right)^2 \left[\frac{1}{E(P_e)} + \frac{1}{E(P_c)} \right] \quad (70)$$

where

$$E(P_i) = \left[\frac{1 - e^{-\lambda_i^* \tau} (1 - e^{-\lambda_i^* T})}{\lambda_i^* T} \right] \left(\frac{\lambda_i}{\lambda_i^*} \right) \quad i = e, c \quad (71)$$

and where n is the sample size in each group, θ is the hazard ratio, and $\lambda_i = \lambda_i + \phi_i$, $i = e, c$. Several similar works on sample size and power determination under the exponential distribution are available in the literature.^[22]

SAMPLE SIZE BASED ON TREATMENT VARIANCE

Sometimes, a clinical trial will be proposed to test the hypothesis that an experimental drug reduces variability of the key outcome variable as compared to a control. It is convenient to assume that the key outcome variable is normally distributed, or at least asymptotically. The F -test method, which is commonly used to assess whether two variances are equal, compares the two treatments in terms of the ratio $\lambda = \sigma_e / \sigma_c$, where e and c denote experiment and control, respectively; or equivalently, the percentage difference $\Delta = (\lambda - 1) \times 100\%$. Therefore, the hypothesis becomes $H_0: \lambda = 1$ versus $H_a: \lambda \neq 1$. For a significance level of α , a power of $(1 - \beta)$, and a two tailed test, the sample size per arm, n , can be computed by the following quick and satisfactory approximation formula if a clinically important percentage difference Δ is specified

$$n \equiv 2 + \left((z_{\alpha/2} + z_\beta) / \log_e \lambda \right)^2 \quad (72)$$

where z_γ is the $(1 - \gamma)$ percentile of the standard normal distribution. Since $\log_e \lambda = -\log_e (1/\lambda)$, the formula gives the same estimate n whether λ is expressed as σ_e / σ_c or as σ_c / σ_e (see Ref. [23]).

SAMPLE SIZE BASED ON CORRELATION

In observational studies, correlation can be the subject of analysis. We assume the outcome variable is normally distributed, or at least asymptotically. Usually there are two types of hypotheses for testing correlation: (1) whether a true correlation actually exists, $H_0: \rho = 0$ versus $H_a: \rho = \rho_1 \neq 0$; (2) whether the two correlations are significantly different, $H_0: \mu_0 = (\rho_e - \rho_c) = 0$ versus $H_a: \mu_1 = (\rho_e - \rho_c) \neq 0$, where e and c denote experiment and control, respectively. The simplest approach to such problems is to employ Fisher's arctanh transformation:

$$C(r) = 1/2 \log_e \left(\frac{1+r}{1-r} \right) \quad (73)$$

Given a sample correlation r based on N observations, which is distributed about an actual correlation value ρ , then $C(r)$ is normally distributed with mean $C(\rho)$ and variance $\sigma^2 = 1/(N-3)$. The transformation of r to C (and vice versa) is widely tabulated.

A Single Correlation

To test hypothesis $H_0: \rho = 0$ versus $H_a: \rho = \rho_1 \neq 0$, we use the test statistic $Z = C(r) \sqrt{N-3}$. Under H_0 , Z is $N(0,1)$. The sample size then can be obtained by using the following equation:

$$\sqrt{N-3} C(\rho_1) = z_\alpha + z_\beta \quad (74)$$

Two Independent Correlations

In detecting a difference in correlations obtained from two independent samples, the null hypothesis $H_0: \mu_0 = 0$ is tested by using the statistic: $Z = [C(r_e) - C(r_c)] / \Sigma_0^2$, where $\Sigma_0^2 = N^{-1}(Q_e^{-1} + Q_c^{-1})$, $n_e - 3 = Q_e N$ and $n_c - 3 = Q_c N$. And under H_0 , Z is $N(0,1)$. The correlation r_e and r_c are obtained from two samples of size n_e and n_c such as $r_e = r_{e(uv)}$ and $r_c = r_{c(uv)}$ for variables u and v in groups e and c . The total sample size can be obtained by solving the following equation:

$$\frac{\sqrt{N} |C(\rho_e) - C(\rho_c)|}{\sqrt{Q_e^{-1} + Q_c^{-1}}} = z_\alpha + z_\beta \quad (75)$$

Note that N from the above equation will actually be 6 less than that actually needed because $n_e + n_c - 6 = N$ (see Ref. [1]).

REESTIMATING SAMPLE SIZE WITHOUT UNBLINDING

Sample size estimation is a key step for a successful clinical trial. Estimation of sample size in clinical trials depends on the level of significance, α , the power of the trial, $1-\beta$, the minimum detectable difference, δ , all of which are known, and on the knowledge of the variability of the primary response variable, which is usually uncertain to medical researchers. The values of the variability measures usually are guessed or taken from the results of previous trials. In either case, they are subject to uncertainty and may be materially smaller or larger than the true values. Overstating the true variability causes the trial to be larger than it should be, implying unnecessary expenditure of resources or a potential ethical problem due to exposure of more patients than necessary to an inferior treatment. Understating the true variability inflates the Type II error rate, β , which means decreasing the power of the trial, and therefore increasing the likelihood of an inconclusive trial when the treatment effect is real. The resource cost and unproductive patient exposure resulting from an inconclusive trial are much greater than when the variability is overstated. Even with previous data available, one must exercise caution regarding possible differences between the trials in terms of patient population, disease severity, diagnostic criteria, medical procedures, and other study conditions. It is therefore desirable to reestimate the sample size using interim data of the trial under study. It is also important to keep the treatment code blind in an interim estimation to avoid the introduction of any potential (conscious or unconscious) bias during the conduct and monitoring of a clinical trial, especially for those trials with which there is no independent, external data monitoring committee involved.

Normally Distributed Outcomes

Consider a clinical trial that compares two treatments, the null hypothesis $H_0: \mu_1 = \mu_2$ ordinarily would be tested against the alternative $H_a: \mu_1 \neq \mu_2$ using a Student t -test. Given the significance level, α , the power of the trial, $1-\beta$ and the minimum detectable difference, δ , the total sample size would be determined from

$$N = \frac{4\tilde{\sigma}^2(z_{\alpha/2} + z_\beta)^2}{\delta^2} \quad (76)$$

where $\tilde{\sigma}^2$ is the estimate of σ^2 , the within-group variance, and z_γ is the $(1-\gamma)$ percentile of the standard normal distribution.

Suppose that the sample size will be reconsidered after n ($<N$) observations without knowing the treatment assignments, that means we know the observation come from a treatment group (1 or 2), but we do not know the treatment identification of the treatment group. With the reestimate,

$\hat{\sigma}^2$, of σ^2 the within-group variance, one can determine the actual sample size as

$$N' = N\hat{\sigma}^2/\tilde{\sigma}^2 \quad (77)$$

where $\tilde{\sigma}^2$ is the estimate of σ^2 at the beginning of the study.

The Expectation Maximization (EM) algorithm will be used to reestimate σ^2 without unblinding. Since the treatment identifications are unknown, any of the interim observations x_i , $i = 1, \dots, n$ could be in either treatment group, so that the treatment assignments are “missing at random.” Let τ_i denote the treatment group membership indicator

$$\tau_i = 1 \text{ (0)}$$

if sample number i is in treatment group 1 (group2) $\tau_1, \dots, \tau_n$ are independent random variables with $\Pr(\tau_i=1)=0.5$. Given a τ_i value, x_i ($i=1, \dots, n$) has a normal distribution with density

$$f(x_i|\tau_i, \mu_1, \mu_2, \sigma) \propto \frac{1}{\sigma} \exp \left\{ -\frac{1}{\sigma^2} [\tau_i(x_i - \mu_1)^2 + (1 - \tau_i)(x_i - \mu_2)^2] \right\} \quad (78)$$

The expression for the conditional probability (or expectation) of τ_i given x_i therefore is

$$\Pr(\tau_i = 1|x_i) = 1/\{1 + \exp[(\mu_1 - \mu_2) \times (\mu_1 + \mu_2 - 2x_i)/2\sigma^2]\} \quad (79)$$

The log-likelihood of the interim observations follows from Eq. 78

$$l = n \log \sigma + \left\{ \sum_{i=1}^n [\tau_i(x_i - \mu_1)^2 + (1 - \tau_i)(x_i - \mu_2)^2] \right\} / 2\sigma^2 \quad (80)$$

The “E” step of the EM algorithm for estimating σ consists of substituting “current” estimates of μ_1 , μ_2 , and σ into Eq. 79 to obtain provisional values for the expectations of the τ_i . The “M” step consists of obtaining maximum likelihood estimates of μ_1 , μ_2 , and σ after replacing the τ_i in Eq. 80 with their provisional expectations. The “E” and “M” steps are repeated until the value of σ^2 stabilizes; the resulting value is the estimate, $\hat{\sigma}^2$, of σ^2 required in Eq. 77. This process estimates the variance satisfactorily, but does not provide a reliable estimate of the difference between the treatment group means (see Ref. [24]).

Binomial Distributed Outcomes

Consider a clinical trial that compares the effect of two treatments on a disease based on a binary outcome (y), for which we use the generic term “event” ($y = 1$) versus

“nonevent” ($y=0$). Denote p_1 and p_2 as the true “event” rates for the two treatment groups, p_1^* and p_2^* , as the estimates of p_1 and p_2 , respectively, $\sigma(p_1, p_2) = (p_1 + p_2)/2$ as the average event rate, and $\sigma(p_1, p_2) = (p_1 + p_2)/2$ as the treatment difference. The hypotheses to test are: $H_0: p_1 = p_2$ versus $H_a: p_1 \neq p_2$. For power $(1-\beta)$ and significant level α , the sample size per treatment group is determined by

$$n = \frac{2(z_{\alpha/2} + z_\beta)^2 \sigma(1-\sigma)}{\delta^2} \equiv 2(z_{\alpha/2} + z_\beta)^2 \lambda(\sigma, \delta) \quad (81)$$

where z_γ is the $(1-\gamma)$ percentile of the standard normal distribution, and $\lambda(\sigma, \delta) = \sigma(1-\sigma)\delta^2$ is the noncentrality parameter, $\delta \neq 0$. The estimated sample size is obtained by substituting p_1^* and p_2^* in Eq. 81.

We now describe a method that updates the estimation of p_i using interim data from the trial, without breaking the treatment code of the individual patients. We design the trial with a simple, random stratification scheme. For a multicenter trial, this stratification is within each center. Patients are first randomly assigned to either stratum A or B. Since this stratification is not based on any of the patient’s baseline characteristics, it is a “dummy” stratification. We use it only at the interim stage for reestimation and at the final stage we simply ignore it without affecting the regular inference. In stratum A, patients are randomly allocated to treatment group of $i = 1$ with a probability π and to treatment group of $i = 2$ with a probability $1-\pi$; $0 < \pi < 1$. In stratum B, we do the opposite; patients are randomly allocated to treatment group of $i = 1$ with a probability $1-\pi$ and to treatment group of $i = 2$ with a probability π . Hence, we maintain the overall balance of the treatment allocation. It is clear that we should avoid $\pi = 0.5$ because it defeats the purpose of the stratification.

We conduct an interim analysis after the trial is half-way completed as originally planned, that is, when the outcome data (y) are available from a total of n^* patients. Note that among these n^* patients, presumably we should have about $n^*/2$ from each treatment group and also $n^*/2$ from each stratum due to the randomization procedure applied to treatment and stratum, but these n^* patients’ treatment codes remain masked. We report only the pooled event rates for each stratum, without knowing treatment codes, and we estimate the event rates p_1 and p_2 as follows.

We use the result of stratum A to estimate $\theta_1 = P(y_j = 1 | \text{patient} \in \text{stratum A}) = \pi p_1 + (1-\pi)p_2$, and that of stratum B to estimate $\theta_2 = P(y_j = 1 | \text{patient} \in \text{stratum B}) = (1-\pi)p_1 + \pi p_2$. Let the observed event rates in the two strata be $\hat{\theta}_k$, which are unbiased estimators of θ_k , $k=1,2$. Thus, we have the following pair 2 of equations:

$$\begin{aligned} \pi \hat{p}_1 + (1-\pi) \hat{p}_2 &= \hat{\theta}_1 \\ (1-\pi) \hat{p}_1 + \pi \hat{p}_2 &= \hat{\theta}_2 \end{aligned} \quad (82)$$

Solving Eq. 82 for p_1 and p_2 , we have the unbiased estimators of the true event rates for the treatment group,

being weighted averages of the pooled rates from the two strata. We then update the sample size by substituting p_i for p_i^* , $i = 1, 2$ in Eq. 81. In practice, we generally recommend setting π near the middle of 0 and 0.5, e.g., $\pi = 0.2$, to provide reasonable protection of power, and, at the same time, for easy conduct of a trial (see Ref. [25]).

CONCLUSION

Although this entry covers many formulas and/or procedures for sample size determination in clinical research, there are still many areas such as sample size requirement in genomic studies and clinical studies utilizing adaptive trial design, which are not covered in this entry. More details can be found in Chow et al.^[26]

At the interim examination, the estimated variability could turn out to be much less than was anticipated in designing the trial. When this happens, one can terminate the trial without affecting α materially if the interim sample size is adequate. However, this ordinarily would not be advisable in practice. Confirmatory trials seldom have solely the objective of detecting a difference between treatments with respect to a single measurement. Safety and tolerability areas important as efficacy, which itself often needs to be described with more than one measurement. Reducing the sample size could imperil the sensitivity of the trial for detecting clinically meaningful differences with respect to “secondary,” but still important, measurements, and would reduce the sensitivity of the trial for assessing safety and tolerability (see Ref. [24]).

Abstract

The equivalence assessment may be conducted through a three-arm clinical trial (namely test, reference and placebo) and it usually consists of three tests. The first two tests are to demonstrate the superiority of the test and the reference treatment to placebo, and they are followed by the equivalence assessment between the test and the reference treatment. With continuous response, equivalence is commonly defined in terms of mean difference, mean ratio or ratio of mean differences, i.e. the mean difference of the test and placebo to mean difference of the reference and placebo. These equivalence tests can be performed with both hypothesis testing approach and confidence interval approach. The advantage of applying the equivalence test by ratio of mean differences is that it can test both superiority of the test treatment over placebo and equivalence between the test and the reference simultaneously through a single hypothesis. In this article, we derive the test statistics and the power function for the ratio of mean differences hypothesis and solve the required sample size for a three-arm clinical trial. Examples of required sample size are given in this article, and are compared with the required sample size by the traditional mean difference equivalence test. After a careful examination, we suggest to increase the power of the ratio of mean differences approach by appropriately adjusting the lower limit of the equivalence interval.

Keywords: Equivalence test; Superiority; Three-arm clinical trial; Power; Bioequivalence.

INTRODUCTION

When a clinical trial is designed to assess the equivalence of the test and reference products based on therapeutic endpoints, it often involves three arms, namely, placebo, test, and reference arms. This type of three-arm trial is also called an active control trial with a placebo arm. The purpose of including the placebo arm is to establish the efficacy of the test treatment, as well as to validate the assay sensitivity through the effect of the reference treatment (Pigeot et al., 2003). When the response is continuous, equivalence is commonly established by showing that either the difference or the ratio of two treatment means is bounded within a prespecified equivalence margin, as discussed in many papers and FDA bioequivalence guidance (Kieser, 1999; Food and Drug Administration [FDA], 2001; Chow and Liu, 2008; Kang and Chow, 2013).

Conventionally, an equivalence test between the test and reference treatments is conducted only after showing

the efficacy of both the test and the reference treatments in the study's population (Koch and Rohmel, 2004). Such a three-arm trial has been discussed in Tsong et al. (2004) with the equivalence defined by the mean ratio. It can be shown that passing the equivalence test alone does not necessarily imply the positive effect of the test treatment or the reference treatment against the placebo as defined in a superiority trial. In addition, the results of a two-arm equivalence assessment by the mean difference or by the mean ratio provide little information about the relative efficacy of the test treatment and the reference treatment. To address these issues, this article describes an equivalence assessment based on the ratio of mean differences, that is, the mean difference of the test and the placebo divided by the mean difference of the reference and the placebo. Furthermore, when assay sensitivity is well established prior to the trial, it implies that the reference treatment is better than the placebo. In this case, one may simultaneously determine the equivalence between the test and the reference and the superiority of the test treatment over the

placebo by postulating a single hypothesis using the ratio of mean differences test.

BACKGROUND

Two-Arm Equivalence Test Based on Mean Difference or Mean Ratio

In a two-arm parallel design, equivalence is commonly established by showing that either the mean difference or the mean ratio of two treatments is bounded within a pre-specified equivalence interval when the response are normally distributed and the margin is fixed (Chow and Liu, 2008; Kang and Chow, 2013). In this article, the test arm and the reference arm are denoted by X_T and X_R respectively. X_T and X_R are assumed to be normally distributed with $X_T \sim N(\mu_T, \sigma_T^2)$ and $X_R \sim N(\mu_R, \sigma_R^2)$, where X_T and X_R are independent. The corresponding hypotheses of mean difference and mean ratio equivalence tests are given by,

$$\begin{aligned} H_0^D : \delta_1^* \geq \mu_T - \mu_R \quad \text{or} \quad \mu_T - \mu_R \geq \delta_2^* \quad \text{vs.} \\ H_a^D : \delta_1^* < \mu_T - \mu_R < \delta_2^* \end{aligned} \quad (1)$$

or

$$H_0^R : \frac{\mu_T}{\mu_R} \leq \delta_1 \quad \text{or} \quad \frac{\mu_T}{\mu_R} \geq \delta_2 \quad \text{vs.} \quad H_a^R : \delta_1 < \frac{\mu_T}{\mu_R} < \delta_2 \quad (2)$$

where (δ_1^*, δ_2^*) and (δ_1, δ_2) are the pre-specified equivalence intervals. These two-sided hypotheses (1) and (2) are equivalent to the following two one-sided hypotheses,

$$H_{01}^D : \mu_T - \mu_R \leq \delta_1^* \quad \text{vs.} \quad H_{a1}^D : \mu_T - \mu_R > \delta_1^* \quad (3)$$

$$H_{02}^D : \mu_T - \mu_R \geq \delta_2^* \quad \text{vs.} \quad H_{a2}^D : \mu_T - \mu_R < \delta_2^* \quad (4)$$

and

$$H_{01}^R : \frac{\mu_T}{\mu_R} \leq \delta_1 \quad \text{vs.} \quad H_{a1}^R : \frac{\mu_T}{\mu_R} > \delta_1 \quad (5)$$

$$H_{02}^R : \frac{\mu_T}{\mu_R} \geq \delta_2 \quad \text{vs.} \quad H_{a2}^R : \frac{\mu_T}{\mu_R} < \delta_2 \quad (6)$$

Schuurmann (1987) has demonstrated that a two-sided 5% level test of hypothesis (1) has the same decision rule as two one-sided 5% level tests of hypotheses (3) and (4) under normality assumption. Meanwhile, two-sided 5% level test of hypothesis (2) has the same decision rule as two one-sided 5% level tests for hypotheses (5) and (6) under normality or log-normality assumption.

To assess the equivalence by mean difference (1), the test statistics can be derived as

$$T_i^D = \frac{\bar{X}_T - \bar{X}_R - \delta_i}{se(\bar{X}_T - \bar{X}_R)} = \frac{\bar{X}_T - \bar{X}_R - \delta_i}{\sqrt{\frac{s_T^2}{n_T} + \frac{s_R^2}{n_R}}} \sim t_v, \quad i = 1 \text{ or } 2, \quad (7)$$

where $\bar{X}_T$ and $\bar{X}_R$ denote the sample mean of the test and the reference arm respectively. Under null hypotheses of $H_{0i}^D : \mu_T - \mu_R - \delta_i = 0$, T_i^D follows a central t -distribution with degrees of freedom, v , where v is approximated by Satterthwaite approach (Satterthwaite, 1946),

$$v = \frac{\left(\frac{\sigma_T^2}{n_T} + \frac{\sigma_R^2}{n_R} \right)^2}{\left(\frac{\sigma_T^4/n_T^2}{n_T - 1} + \frac{\sigma_R^4/n_R^2}{n_R - 1} \right)}.$$

For equal variances with $\sigma_T = \sigma_R = \sigma$, the test statistics are

$$T_i^D = \frac{\bar{X}_T - \bar{X}_R - \delta_i}{se(\bar{X}_T - \bar{X}_R)} = \frac{\bar{X}_T - \bar{X}_R - \delta_i}{\sqrt{S_{pool}^2 \left(\frac{1}{n_T} + \frac{1}{n_R} \right)}} \sim t_v, \quad i = 1 \text{ or } 2 \quad (8)$$

where $S_{pool}^2 = \frac{(n_T - 1)S_T^2 + (n_R - 1)S_R^2}{n_T + n_R - 2} \sim \frac{\sigma^2 \chi_v^2}{v}$ with degrees

of freedom $v = n_T + n_R - 2$. Equivalence in terms of mean difference can be concluded if $T_1^D \geq t_{\alpha, v}$ and $T_2^D \leq -t_{\alpha, v}$ with $t_{\alpha, v}$ to be $(1 - \alpha)100$ th-percentile of the central t -distribution with degrees of freedom v .

Using the same notations, for testing the mean ratio (2), assuming positive treatment effect of the reference treatment (i.e. $\mu_R > 0$), one can multiply μ_R on both sides, then the two hypotheses can be expressed as a linear combination of treatment means, μ_R and μ_T :

$$H_{01}^R : \mu_T - \delta_1 \mu_R \leq 0 \quad \text{vs.} \quad H_{a1}^R : \mu_T - \delta_1 \mu_R > 0$$

$$H_{02}^R : \mu_T - \delta_2 \mu_R \geq 0 \quad \text{vs.} \quad H_{a2}^R : \mu_T - \delta_2 \mu_R < 0$$

The following test statistics can be applied for testing each null hypothesis, (5) and (6).

$$T_i^R = \frac{\bar{X}_T - \delta_i \bar{X}_R}{se(\bar{X}_T - \delta_i \bar{X}_R)} = \frac{\bar{X}_T - \delta_i \bar{X}_R}{\sqrt{\frac{s_T^2}{n_T} + \delta_i^2 \frac{s_R^2}{n_R}}} \sim t_{v_i}, \quad i = 1 \text{ or } 2. \quad (9)$$

Under null hypotheses $H_{0i}^R : \mu_T - \delta_i \mu_R = 0$, T_i^R follow central t -distributions with degrees of freedom

$$v_i = \frac{\left(\frac{\sigma_T^2}{n_T} + \frac{\delta_i^2 \sigma_R^2}{n_R} \right)^2}{\left(\frac{\sigma_T^4/n_T^2}{n_T - 1} + \frac{\delta_i^4 \sigma_R^4/n_R^2}{n_R - 1} \right)}, \quad \text{which is approximated by}$$

Satterthwaite approach (Satterthwaite, 1946). For equal variances, when $\sigma_T = \sigma_R = \sigma$, the test statistics are

$$T_i^R = \frac{\bar{X}_T - \delta_i \bar{X}_R}{se(\bar{X}_T - \delta_i \bar{X}_R)} = \frac{\bar{X}_T - \delta_i \bar{X}_R}{\sqrt{S_{pool}^2 \left(\frac{1}{n_T} + \delta_i^2 \frac{1}{n_R} \right)}} \sim t_v \quad i = 1 \text{ or } 2 \quad (10)$$

where $S_{pool}^2 = \frac{(n_T - 1)S_T^2 + (n_R - 1)S_R^2}{n_T + n_R - 2} \sim \frac{\sigma^2 X_v^2}{v}$ with degrees of freedom $v = n_T + n_R - 2$. Equivalence in terms of mean ratio can be concluded if $T_1^R \geq t_{\alpha, v}$ and $T_2^R \leq -t_{\alpha, v}$.

Under alternative hypothesis and with unequal variances, both T_i^D and T_i^R given in (7) and (9) follow bivariate non-central t-distribution approximately (Owen, 1965). For the mean difference test (1), under the alternative space that $\delta_1^* < \mu_T - \mu_R < \delta_2^*$, the non-centrality parameters for T_i^D are $\theta_i = \frac{\mu_T - \mu_R - \delta_i}{\sqrt{\frac{\sigma_T^2}{n_T} + \frac{\sigma_R^2}{n_R}}}$, $i=1$ or 2 with correlation

coefficient 1 between T_i^D . For the mean ratio test (2), under the alternative space that $\delta_1 < \frac{\mu_T}{\mu_R} < \delta_2$, the non-

centrality parameters for T_i^R are $\theta_i = \frac{\mu_T - \delta_i \mu_R}{\sqrt{\frac{\sigma_T^2}{n_T} + \delta_i^2 \frac{\sigma_R^2}{n_R}}}$, $i=1$ or 2 with correlation coefficient $\frac{\frac{\sigma_T^2}{n_T} + \delta_1 \delta_2 \frac{\sigma_R^2}{n_R}}{\sqrt{\frac{\sigma_T^2}{n_T} + \delta_1^2 \frac{\sigma_R^2}{n_R}} \sqrt{\frac{\sigma_T^2}{n_T} + \delta_2^2 \frac{\sigma_R^2}{n_R}}}$

between T_i^R . The degrees of freedoms for both tests are derived earlier using Satterthwaite approach.

Under the assumption of equal variance and equal sample size per arm, the non-centrality parameters and the correlation coefficient of T_i^D and T_i^R can be simplified as $\theta_i = \frac{\mu_T - \mu_R - \delta_i}{\sqrt{\frac{2\sigma^2}{n}}}$ and $\theta_i = \frac{\mu_T - \delta_i \mu_R}{\sqrt{\frac{\sigma^2}{n}(1 + \delta_i^2)}}$ with correlation

coefficient 1 and $\frac{1 + \delta_1 \delta_2}{\sqrt{1 + \delta_1^2} \sqrt{1 + \delta_2^2}}$ respectively. The power function for both tests is given as

$$P[T_1 \geq t_{\alpha, 2n-2} \text{ and } T_2 \leq -t_{\alpha, 2n-2} | H_a] \\ = Q(\infty, -t_{\alpha, 2n-2}, \theta_1, \theta_2, \rho) - Q(t_{\alpha, 2n-2}, -t_{\alpha, 2n-2}, \theta_1, \theta_2, \rho)$$

$$\text{where } Q(a, b, c, d, e) = \frac{1}{\Gamma(n-1) \cdot 2^{n-2}} \int_0^\infty \Phi_2\left(\frac{ay}{\sqrt{2n-2}} - c, \frac{by}{\sqrt{2n-2}} - d, e\right) y^{2n-3} e^{-\frac{y^2}{2}} dy$$

$$\Phi_2(x, y, e) = \frac{1}{2\pi\sqrt{1-e^2}} \int_{-\infty}^x \int_{-\infty}^y \exp\left(-\frac{u^2 - 2euv + v^2}{2(1-e^2)}\right) dv du$$

Hauschke et al. (1999) derived the above power function for the mean ratio test.

THREE-ARM EQUIVALENCE TEST BASED ON MEAN DIFFERENCE OR MEAN RATIO

Equivalence between the test and reference treatments may be claimed if the null hypotheses of (1) or (2) are rejected

at $\alpha=5\%$ level and knowing that $\mu_R > \mu_p$ and $\mu_T > \mu_p$, where X_p is defined as the response from placebo arm, and $X_p \sim N(\mu_p, \sigma_p^2)$. Assume a higher response score indicates a more favorable outcome in this article. In order to establish assay sensitivity of the reference treatment (i.e. $\mu_R > \mu_p$) and efficacy of the test treatment (i.e. $\mu_T > \mu_p$) before equivalence assessment between the test and reference treatments, one may often have to carry out a parallel clinical trial with three arms including the test, the reference and placebo arms. In such a three-arm trial, conventionally, prior to test for equivalence hypotheses (1) or (2), one needs to test the following two superiority hypotheses at 2.5% level of α ,

$$H_0: \mu_R - \mu_p \leq 0 \quad \text{vs.} \quad H_a: \mu_R - \mu_p > 0 \quad (11)$$

$$H_0: \mu_T - \mu_p \leq 0 \quad \text{vs.} \quad H_a: \mu_T - \mu_p > 0. \quad (12)$$

The first superiority test is to validate assay sensitivity of the reference treatment. The second superiority test is to establish efficacy of the test treatment. After rejecting both superiority tests of (11) and (12), one may move on to the equivalence assessment based on mean difference (1) or mean ratio (2). From the historical data, if the reference treatment is consistently superior to placebo, one may assume that $\mu_R - \mu_p > 0$, and skip the test in (11). Thus the conventional three-arm equivalence assessment can be reduced to the following test (A) or test (B).

$$\text{A. } H_0: \mu_T - \mu_p \leq 0 \quad \text{vs.} \quad H_a: \mu_T - \mu_p > 0 \quad \alpha_1 = 2.5\% \\ H_0^D: \delta_1^* \geq \mu_T - \mu_R \quad \text{or} \quad \mu_T - \mu_R \geq \delta_2^* \quad \text{vs.} \\ H_{a1}^D: \delta_1^* < \mu_T - \mu_R < \delta_2^* \quad \alpha_2 = 5\%$$

$$\text{B. } H_0: \mu_T - \mu_p \leq 0 \quad \text{vs.} \quad H_a: \mu_T - \mu_p > 0 \quad \alpha_1 = 2.5\% \\ H_0^R: \frac{\mu_T}{\mu_R} \leq \delta_1 \quad \text{or} \quad \frac{\mu_T}{\mu_R} \geq \delta_2 \quad \text{vs.} \\ H_a^R: \delta_1 < \frac{\mu_T}{\mu_R} < \delta_2 \quad \alpha_2 = 5\%$$

THREE-ARM EQUIVALENCE TEST BASED ON RATIO OF MEAN DIFFERENCES

When the interest of an equivalence assessment involves whether the efficacy of the test treatment remains within given percentages of the efficacy of the reference treatment, one may consider assessing the equivalence based on ratio of mean differences, i.e. relative efficacy. With this objective, we can test the following hypothesis instead of (1) or (2).

$$H_0: \frac{(\mu_T - \mu_p)}{(\mu_R - \mu_p)} \leq \delta_1 \quad \text{or} \quad \frac{(\mu_T - \mu_p)}{(\mu_R - \mu_p)} \geq \delta_2 \quad \text{versus} \\ H_a: \delta_1 < \frac{(\mu_T - \mu_p)}{(\mu_R - \mu_p)} < \delta_2 \quad (13)$$

To simplify the notation, let M be the sample mean difference between the test treatment and placebo, and Q be the sample mean difference between the reference treatment and placebo. Assuming the responses from the test arm, reference arm and placebo arm are mutually independent, the joint distribution of M and Q is given by

$$\begin{pmatrix} M \\ Q \end{pmatrix} \sim MN_2 \left(\begin{pmatrix} \mu_T - \mu_P \\ \mu_R - \mu_P \end{pmatrix}, \begin{pmatrix} \frac{\sigma_T^2}{n_T} + \frac{\sigma_P^2}{n_P} & \frac{\sigma_P^2}{n_P} \\ \frac{\sigma_P^2}{n_P} & \frac{\sigma_R^2}{n_R} + \frac{\sigma_P^2}{n_P} \end{pmatrix} \right)$$

The correlation coefficient between M and Q is

$$\rho^{MQ} = \frac{\sigma_P^2}{n_P \sqrt{\frac{\sigma_T^2}{n_T} + \frac{\sigma_P^2}{n_P}} \sqrt{\frac{\sigma_R^2}{n_R} + \frac{\sigma_P^2}{n_P}}}.$$

The two one-sided hypotheses of the equivalence test (13) are therefore

$$H_{01} : \frac{\mu_M}{\mu_Q} \leq \delta_1 \quad \text{vs.} \quad H_{a1} : \frac{\mu_M}{\mu_Q} > \delta_1 \quad (14)$$

$$H_{02} : \frac{\mu_M}{\mu_Q} \geq \delta_2 \quad \text{vs.} \quad H_{a2} : \frac{\mu_M}{\mu_Q} < \delta_2 \quad (15)$$

where $\mu_M = \mu_T - \mu_P$, $\mu_Q = \mu_R - \mu_P$. Assuming that $\mu_Q > 0$ and multiplying by μ_Q on both sides, (14) and (15) can be further rewritten as

$$H_{01} : \mu_M - \delta_1 \mu_Q \leq 0 \quad \text{vs.} \quad H_{a1} : \mu_M - \delta_1 \mu_Q > 0 \quad (16)$$

$$H_{02} : \mu_M - \delta_2 \mu_Q \geq 0 \quad \text{vs.} \quad H_{a2} : \mu_M - \delta_2 \mu_Q < 0 \quad (17)$$

The test statistic for each hypothesis is

$$T_i = \frac{M - \delta_i Q}{Se(M - \delta_i Q)} = \frac{\bar{X}_T - \delta_i \bar{X}_R - (1 - \delta_i) \bar{X}_P}{\sqrt{\frac{S_T^2}{n_T} + \delta_i^2 \frac{S_R^2}{n_R} + (1 - \delta_i)^2 \frac{S_P^2}{n_P}}}, \quad i = 1 \text{ or } 2.$$

Under the null hypotheses, when $H_{0i} : \mu_M - \delta_i \mu_Q = 0$, T_1 and T_2 follow bivariate t-distribution with the degrees of freedom ν_i approximated by

$$\nu_i = \frac{\left(\frac{\sigma_T^2}{n_T} + \frac{\delta_i^2 \sigma_R^2}{n_R} + \frac{(1 - \delta_i)^2 \sigma_P^2}{n_P} \right)^2}{\left(\frac{\sigma_T^4 / n_T^2}{n_T - 1} + \frac{\delta_i^4 \sigma_R^4 / n_R^2}{n_R - 1} + \frac{(1 - \delta_i)^4 \sigma_P^4 / n_P^2}{n_P - 1} \right)}, \quad i = 1 \text{ or } 2 \quad (\text{Satterthwaite, 1946}).$$

To claim the equivalence of the test and the reference treatments, one needs to reject both null hypotheses, H_{01} and H_{02} , with $T_1 \geq t_{\alpha, \nu_1}$ and $T_2 \leq -t_{\alpha, \nu_2}$.

Under the alternative hypothesis, T_1 and T_2 approximately follow bivariate non-central t-distribution with the non-centrality parameters $\theta_i = \frac{\mu_M - \delta_i \mu_Q}{Sd(M - \delta_i Q)} = \frac{(\delta^* - \delta_i) \mu_Q}{Sd(M - \delta_i Q)}$

where $\delta^* = \frac{\mu_M}{\mu_Q}$ and $\delta_1 < \delta^* < \delta_2$. The covariance of numerators, $M - \delta_1 Q$ and $M - \delta_2 Q$ is

$$Cov(M - \delta_1 Q, M - \delta_2 Q) = \frac{\sigma_T^2}{n_T} + \delta_1 \delta_2 \frac{\sigma_R^2}{n_R} + (1 + \delta_1 \delta_2 - \delta_1 - \delta_2) \frac{\sigma_P^2}{n_P}$$

and the correlation coefficient is

$$\rho = \frac{\frac{\sigma_T^2}{n_T} + \delta_1 \delta_2 \frac{\sigma_R^2}{n_R} + \frac{\sigma_P^2}{n_P} (1 + \delta_1 \delta_2 - \delta_1 - \delta_2)}{\sqrt{\frac{\sigma_T^2}{n_T} + \delta_1^2 \frac{\sigma_R^2}{n_R} + \frac{\sigma_P^2}{n_P} (1 - \delta_1)^2} \sqrt{\frac{\sigma_T^2}{n_T} + \delta_2^2 \frac{\sigma_R^2}{n_R} + \frac{\sigma_P^2}{n_P} (1 - \delta_2)^2}}. \quad (18)$$

With equal sample variance and equal sample size, the test statistics are given by

$$T_i = \frac{M - \delta_i Q}{Se(M - \delta_i Q)} = \frac{\bar{X}_T - \delta_i \bar{X}_R - (1 - \delta_i) \bar{X}_P}{\sqrt{\frac{S_{pool}^2}{n} [1 + \delta_i^2 + (1 - \delta_i)^2]}}, \quad i = 1 \text{ or } 2 \quad (19)$$

where $S_{pool}^2 = \frac{S_T^2 + S_R^2 + S_P^2}{3} \sim \frac{\sigma^2 \chi_v^2}{v}$ and degrees of freedom $\nu = 3n - 3$. Under the null hypothesis, when $H_{0i} : \mu_M - \delta_i \mu_Q = 0$, T_1 and T_2 follow bivariate t-distribution with degrees of freedom $\nu = 3n - 3$. The equivalence of the test and reference treatments can be claimed by rejecting both H_{01} and H_{02} by showing that $T_1 \geq t_{\alpha, 3n-3}$ and $T_2 \leq -t_{\alpha, 3n-3}$. Under the alternative hypothesis, T_1 and T_2 follow bivariate non-central t distribution and the non-centrality parameters can be simplified as

$$\theta_i = \left(\frac{\mu_M - \mu_P}{\sigma} \right) \left(\frac{(\delta^* - \delta_i) \sqrt{n}}{\sqrt{1 + \delta_i^2 + (1 - \delta_i)^2}} \right), \quad (20)$$

$$\text{where } \delta^* = \frac{\mu_M}{\mu_Q} \text{ and } \rho = \frac{(2 + 2\delta_1 \delta_2 - \delta_1 - \delta_2)}{\sqrt{[1 + \delta_1^2 + (1 - \delta_1)^2][1 + \delta_2^2 + (1 - \delta_2)^2]}}.$$

The power function of this ratio of mean differences test under the assumption of equal variances and equal sample sizes is given below,

$$P(T_1 \geq t_{\alpha, 3n-3} \text{ and } T_2 \leq -t_{\alpha, 3n-3} | \delta^*, \delta_1, \delta_2, \sigma, \mu_R - \mu_P) = Q(\infty, -t_{\alpha, 3n-3}, \theta_1, \theta_2, \rho) - Q(t_{\alpha, 3n-3}, -t_{\alpha, 3n-3}, \theta_1, \theta_2, \rho)$$

where

$$Q(a, b, c, d, e) = \frac{1}{\Gamma(\frac{3n-3}{2}) \cdot 2^{\frac{3n-5}{2}}} \int_0^\infty \Phi_2 \left(\frac{ay}{\sqrt{3n-3}} - c, \frac{by}{\sqrt{3n-3}} - d, e \right) y^{3n-4} e^{-\frac{y^2}{2}} dy$$

$$\Phi_2(x, y, e) = \frac{1}{2\pi\sqrt{1-e^2}} \int_{-\infty}^x \int_{-\infty}^y \exp\left(-\frac{u^2 - 2euv + v^2}{2(1-e^2)}\right) dv du$$

The required sample size for a given power can be solved by assigning the values of δ^* , δ_1 , δ_2 , σ , $\mu_R - \mu_P$ and α .

Alternatively, the confidence interval approach can be applied and the decision rule becomes $\delta_1^{MR} \geq \delta_1$ and $\delta_2^{MR} \leq \delta_2$

$$\text{for } \delta_i^{MR} = \frac{(MQ - A) \pm \sqrt{2AM^2 + 2AQ^2 - 2AMQ - 3A}}{Q^2 - 2A}, i = 1$$

or 2

$$\text{where } A = t_{\alpha, v}^2 \left(\frac{S_{Pool}^2}{n} \right), v = 3n - 3, M = \bar{X}_T - \bar{X}_P, Q = \bar{X}_R - \bar{X}_P$$

$$\text{if and only if } (\bar{X}_T - \bar{X}_R)^2 + (\bar{X}_T - \bar{X}_P)^2 + (\bar{X}_R - \bar{X}_P)^2 - 3A \geq 0.$$

NUMERICAL EXAMPLE

In this section, the required sample size of the ratio of mean differences test (13) at a 5% significance level under the condition of equal variance and equal sample size per arm is given. Based on the non-centrality parameters, the power function depends on the values of σ and $\mu_R - \mu_P$, and from the historical data, the confidence interval of $\mu_R - \mu_P$ can be derived. In this example, we assume that the 95% confidence interval for $\mu_R - \mu_P$ is (7, 13) with sample mean difference equal to 10. The required sample size is generated by solving the sample size per arm in the power function by assigning $\mu_R - \mu_P$ equal to 7, 10 or 13 and σ equal to 3, 4, 5 or 6. The choice of values for the mean difference and the standard deviation is made by assuming that the proportion of $\frac{\sigma}{\mu_R - \mu_P}$ lies between 0.2 and 0.9. Also, for

illustration purpose, the equivalence margin (δ_1, δ_2) in the following example is given as (0.8, 1.25), which is a common equivalence margin for mean ratio bioequivalence test based on bioavailability data. Biological products are subject to larger variability, and thus different margins may be needed. Margin selection should be carefully discussed within the trial team and also agreed by medical investigators. Table 1 shows the required sample size per arm (test, reference and placebo) to attain a power of 0.8 while $\delta^* = \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} = 0.95, 1$, or $1/0.95$.

From the above table, one may notice that the required sample size is not symmetric about $\delta^* = 1$. When the test treatment mean equals the reference treatment mean, that is $\delta^* = 1$, the required sample sizes are smaller than the required sample size under the condition of $\delta^* = 1/0.95$ and 0.95. However, when the test treatment mean is larger than the reference treatment mean, that is when $\delta^* > 1$, the required sample size is much smaller than the condition in which the reference treatment mean is larger than the test treatment mean, that is when $\delta^* < 1$.

In practice, the assumption of equal sample size per arm may be hard to achieve, as in most three-arm trials, fewer

Table 1 Sample size per arm for the ratio of mean differences test to attain 80% power at a given mean differences ratio δ^* with equal variance and equal sample size and $(\delta_1, \delta_2) = (0.80, 1.25)$ at $\alpha = 0.05$

sample size may be assigned to placebo arm for ethical reason. In addition, the variances may also be different within each arm. In the example, for simplicity purpose, only sample size requirements under the condition of equal sample size and equal variance are given. However, as one may expect that it is the most optimistic case which would give the highest power. Under the condition of unequal sample size between arms and higher variance in any arm would result in a higher total sample size.

SAMPLE SIZE COMPARISON

As discussed in the previous section, assuming that $\mu_R - \mu_P > 0$, equivalence between the test and reference treatments may be claimed if both null hypotheses in (A) are rejected. Replace the mean difference equivalence test in (A) by the ratio of mean differences test, and it becomes

$$\begin{aligned} C. \quad H_{01} : \mu_T - \mu_P \leq 0 \quad \text{vs.} \quad H_{a1} : \mu_T - \mu_P > 0 \quad \alpha_1 = 2.5\% \\ H_{02} : \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} \leq \delta_1 \quad \text{or} \quad \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} \geq \delta_2 \quad \text{vs.} \\ H_{a2} : \delta_1 < \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} < \delta_2 \quad \alpha_2 = 5\% \end{aligned}$$

To compare the sample size of test (A) and test (C), one may give the specific equivalence limit of (δ_1, δ_2) for (C) and the corresponding values of (δ_1^*, δ_2^*) for (A) can be derived. The relationship between the margins δ_i and δ_i^* is given by $\delta_i^* = (\delta_i - 1) \cdot (\mu_R - \mu_P)$. Thus, (A) tests whether the difference of the test treatment mean and the reference treatment mean lies within the interval of $(\delta_1 - 1 \cdot 100\%)$ of $\mu_R - \mu_P$ and $(\delta_2 - 1 \cdot 100\%)$ of $\mu_R - \mu_P$. Table 2 gives the required sample sizes for both test (A) and test (C) under

Table 2 Sample size per arm for the mean difference equivalence test (A) and the ratio of mean differences equivalence test (C) to attain 80% power at a given mean differences ratio δ^* with equal variance and equal sample size where $(\delta_1, \delta_2) = (0.8, 1.25)$ and $(\delta_1^*, \delta_2^*) = (-0.2 \cdot (\mu_R - \mu_P), 0.25 \cdot (\mu_R - \mu_P))$.

the condition of $(\delta_1, \delta_2) = (0.80, 1.25)$ and Table 3 gives the required sample sizes under the condition of $(\delta_1, \delta_2) = (0.5, 2.0)$.

As the results show, the ratio of mean differences test (C) requires a smaller sample size than the mean difference test (A) when $\delta^* < 1$. When $\delta^* = 1$, the sample sizes for both methods are almost identical. However, when $\delta^* > 1$, the sample size for test (C) is larger than test (A). The relationship of power for both test (A) and test (C) is illustrated in Figure 1.

Table 3 Sample size per arm for the mean difference equivalence test (A) and the ratio of mean differences equivalence test (C) to attain 80% power at a given mean differences ratio δ^* with equal variance and equal sample size where $(\delta_1, \delta_2) = (0.5, 2.0)$ and $(\delta_1^*, \delta_2^*) = (-0.5 \cdot (\mu_R - \mu_P), (\mu_R - \mu_P))$.

4	7	66	49	34	26	21	19	17	18	14	17	11	19	11	28
	10	33	24	17	13	11	10	9	9	8	9	6	10	6	14
	13	20	15	11	8	7	6	6	6	5	6	4	6	4	9
5	7	102	77	52	40	32	29	26	27	22	27	17	26	17	43
	10	50	38	26	24	16	15	13	14	11	13	9	15	9	22
	13	30	23	16	12	10	9	8	9	7	8	6	9	6	13
6	7	146	110	75	58	46	42	37	39	31	38	24	42	24	62
	10	72	54	37	29	23	21	19	19	16	19	12	21	12	31
	13	41	32	22	17	14	13	12	12	10	12	8	13	8	19

This figure shows that the power of test (C) is higher than test (A) when $\delta^* < 1$, but test (A) is more powerful than test (C) when $\delta^* > 1$ for the given sample size 20, $\mu_R - \mu_P = 13$ and $\sigma = 3$. This result can be generalized for different parameter values.

Also, one may notice that in Table 2 the required sample size of test (C) is almost identical to the required sample size given in Table 1, which means that adding one more superiority test of the test treatment over placebo to (13) does not have a great impact on the power of the ratio of mean differences equivalence test. This may be because

Figure 1 Power versus mean differences ratio δ^* ranging from 0.85 to 1.15 under the condition of $\mu_R - \mu_P = 13$, $\sigma = 3$ with sample size per arm of 20

by rejecting the null hypothesis of (13), it is concluded that $\delta_1 < \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} < \delta_2$, and this result also implies $\mu_R - \mu_P > 0$ because of the assumption that $\mu_R - \mu_P > 0$ while using a positive δ_1 . This implication is made at a 5% level of α , which is not as stringent as the superiority test at 2.5%. The power of ratio of mean differences test (13) also depends on the value of δ_1 . Thus, if the ratio of mean differences test is conducted with a smaller δ_1 , then the power of the test will increase and the 2.5% superiority test may have some impact on the ratio of mean differences test. One should always choose an appropriate δ_1 with care; otherwise, the equivalence test may not be validated because the equivalence interval may be too wide to conclude equivalence.

We further examined the sample size power relationship for $(\delta_1, \delta_2) = (0.5, 2.0)$. The relationship between the sample size requirement and δ^* remains the same as for $(\delta_1, \delta_2) = (0.8, 1.25)$ as shown in Table 3.

In order to test both superiority of the test treatment over the placebo and equivalence by using only one hypothesis test, one may remove the first superiority test from (C) and change the α level of $H_0 : \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} \leq \delta_1$ vs.

$H_0 : \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} > \delta_1$ from 5% to 2.5%. By doing so, the

lower equivalence margin could also serve as a more stringent superiority test margin, i.e. test (D) below. Not only does the following test (D) serve as the equivalence test, but it also serves as the superiority test of the test treatment over the placebo.

$$\begin{aligned} \text{D. } H_{01} : \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} \leq \delta_1 \quad \text{vs.} \quad H_{a1} : \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} > \delta_1 \quad \alpha_1 = 2.5\% \\ H_{02} : \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} \geq \delta_2 \quad \text{vs.} \quad H_{a2} : \frac{(\mu_T - \mu_P)}{(\mu_R - \mu_P)} < \delta_2 \quad \alpha_2 = 5\% \end{aligned}$$

Table 4 gives the sample size of test (C) vs. test (D). Test (D) requires a larger sample size than test (C) to attain the same power of 0.8. However, the sample size is comparable when the true ratio of mean differences is larger than 1.

CONCLUSION

An equivalence test may be carried out with a clinical trial of three parallel arms (test, reference, and placebo). The conventional approach consists of testing superiority and equivalence. The superiority test part of the process involves analyzing the test treatment and the reference treatment over placebo, while the equivalence test part of the process is to demonstrate whether the test treatment and the reference treatment are equivalent. With continuous responses, the equivalence of the treatments are commonly assessed in terms of either mean difference, mean ratio, or ratio of mean differences, where the test mean and the reference mean are adjusted by the placebo mean.

Table 4 Sample size per arm of test (C) and test (D) to attain 80% power at a given mean differences ratio δ^* with equal variance and equal sample size where $(\delta_1, \delta_2) = (0.8, 1.25)$

	10	171	213	130	146	154	158
	13	102	126	77	87	92	94

When assay sensitivity is validated by showing superiority of the reference over placebo, one may only focus on assessment of superiority of the test treatment over placebo and equivalence between the test and the reference treatments. It is also interesting to know that testing for equivalence using the ratio of mean differences may be more efficient than mean difference between the test and the reference treatments when the true ratio of mean differences is less than 1, i.e. when $(\mu_T - \mu_P) < (\mu_R - \mu_P)$.

When conducting the ratio of mean differences test, under the condition of $(\mu_T - \mu_P) / (\mu_R - \mu_P) > 0$ and a higher response score indicates a more favorable outcome, it directly implies that the test treatment is superior to placebo. In this case, one may waive the superiority test and apply a single ratio of mean differences test, but in order to satisfy the superiority test requirement, one has to perform two one-sided tests with 2.5% level for the lower side and 5% level for the upper side. As indicated in the numerical result, adding the superiority test of test over placebo to the ratio of mean differences test does not affect the power of the test much. By selecting a lower equivalence margin for the ratio of mean differences test which still satisfy the equivalence test criteria can then improve the power of the ratio of mean differences test.

Sample Size Estimation: Generalized Estimating Equations (GEE) Method

Sin-Ho Jung

Department of Biostatistics and Bioinformatics, Duke University, Durham, North Carolina, U.S.A.

Abstract

This entry compares the change rate of repeated measurements over time between two treatment groups. It proposes a closed-form, sample size formula for between-group comparison that can be used when designing a randomized longitudinal study with either continuous or binary outcome variables.

Keywords: AR(1); Compound symmetry; Independent working correlation; Independent missing; Logit link; Missing completely at random; Monotone missing.

INTRODUCTION

Often, in controlled clinical trials, subjects are randomized to two treatment groups and evaluated at a baseline and at intervals across a treatment period. For example, in a study on labor pain, 83 women in labor were randomly assigned to a pain medication group (43 women) or placebo group (40 women). At 30-min intervals, the self-reported amount of pain was marked on a 100mm line, where 0 = no pain and 100 = extreme pain. The maximum number of measurements for each woman was $m = 6$, but there were numerous missing values at later measurement times with a monotone missing pattern. A simple approach to such a study objective may be to estimate and compare the slopes of pain scores over time in two treatment groups. In this study, the outcome variable is continuous.

Genetics vs Environment In Scleroderma Outcome Study (GENISOS) is an observational study designed in collaboration between the University of Texas-Houston Health Science Center, the University of Texas Medical Branch at Galveston, and the University of Texas-San Antonio Health Science Center.^[8] Scleroderma, or systemic sclerosis, is a multi-system disease of unknown etiology characterized by cutaneous and visceral fibrosis, small blood vessel damage, and autoimmune features.^[7] The study subjects are regularly followed to check the occurrence of pulmonary fibrosis. In this case, the outcome is a binary variable.

Typically, repeated measurements from each subject are correlated. Furthermore, the subjects may skip some visits, such that the resulting data are subject to missing. The Generalized Estimating Equations (GEE) method^[6] has been one of the most popular methods to relate repeatedly measured outcome variables with covariates, including

measurement time. If the missing is completely random,^[9] the GEE method provides a consistent regression estimator, to determine whether the working correlation structure specified for the repeated measurements is the true one.

This entry compares the change rate of repeated measurements over time between two treatment groups. We propose a closed-form, sample size formula for between-group comparison that can be used when designing a randomized longitudinal study with either continuous or binary outcome variables. Missing data attenuate the power of tests on the regression coefficients. Our formula accounts for the missing probabilities under an independent or monotone missing pattern. We assume that the working independent correlation model is used in the final data analysis, but the sample size formula is derived to incorporate the influence of the true correlations, especially under AR(1) or compound symmetry.

GENERALIZED ESTIMATING EQUATIONS

Suppose that n_k subjects are allocated to treatment group $k (= 1, 2)$, $n_1 + n_2 = n$. Let, for group k , $N_k = \sum_{i=1}^{n_k} m_{ki}$ denote the total number of observations and $r_k = n_k/n$ the allocation proportion ($r_1 + r_2 = 1$).

For subject i ($i = 1, \dots, n_k$) in group k , let y_{kij} denote the outcome variable at measurement time t_{kij} ($j = 1, \dots, m_{ki}$) with $\mu_{kij} = E(y_{kij})$ that is expressed as

$$g(\mu_{kij}) = a_k + b_k t_{kij},$$

where $g(\cdot)$ is a link function. To simplify the discussions, we use the identity link $g(\mu) = \mu$ for continuous outcome variables and the logit link $g(\mu) = \log\{\mu/(1-\mu)\}$ for binary

outcome variables, but the generalization to the use of other links is simple.

The coefficient b_k represents the change rate per unit time in mean response if y is continuous and in log-odds if y is binary. The measurement times may vary, subject by subject, due to missing measurements, patients' visits for measurements at unscheduled times, loss to follow-up, or other causes. In this article, we assume the missing is completely random by Rubin.^[9]

The repeated measurements (y_{kij} , $1 \leq j \leq m_{ki}$) within each subject tend to be correlated. However, the true correlation structure is usually unknown or of secondary interest. Liang and Zeger^[6] proposed a consistent estimator, called the GEE estimator, based on a working correlation structure. Using either the identity or logit link, the GEE estimator $(\hat{a}_k, \hat{b}_k)$, based on the working independent structure, solves $U_k(a, b) = 0$, where

$$U_k(a, b) = \frac{1}{\sqrt{n_k}} \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} \{y_{kij} - \mu_{kij}(a, b)\} \begin{pmatrix} 1 \\ t_{kij} \end{pmatrix}$$

and $\mu_{kij}(a, b) = g^{-1}(a + bt_{kij})$.

Continuous Outcome Variable Case

In the continuous outcome variable case, we have a closed form solution to $U_k(a, b) = 0$:

$$\hat{b}_k = \frac{\sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} (t_{kij} - \bar{t}_k) y_{kij}}{\sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} (t_{kij} - \bar{t}_k)^2}$$

and $\hat{a}_k = \bar{y}_k - \hat{b}_k \bar{t}_k$, where $\bar{t}_k = N_k^{-1} \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} t_{kij}$ and $\bar{y}_k = N_k^{-1} \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} y_{kij}$.

According to Liang and Zeger,^[6] as $n \rightarrow \infty$, $\sqrt{n_k}(\hat{b}_k - b_k) \rightarrow N(0, v_k)$ in distribution. Here, v_k is consistently estimated by

$$\hat{v}_k = \frac{\sum_{i=1}^{n_k} \left\{ \sum_{j=1}^{m_{ki}} (t_{kij} - \bar{t}_k) \hat{\varepsilon}_{kij} \right\}^2}{\left\{ \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} (t_{kij} - \bar{t}_k)^2 \right\}^2}$$

where $\hat{\varepsilon}_{kij} = y_{kij} - \hat{a}_k - \hat{b}_k t_{kij}$.

Binary Outcome Variable Case

Let $p_{kij} = \mu_{kij}$ in the binary outcome variable case. We have to solve the equation using a numerical method, such as the Newton–Raphson algorithm: at the l -th iteration,

$$\begin{pmatrix} \hat{a}_k^{(l)} \\ \hat{b}_k^{(l)} \end{pmatrix} = \begin{pmatrix} \hat{a}_k^{(l-1)} \\ \hat{b}_k^{(l-1)} \end{pmatrix} + n_k^{-1/2} A_k^{-1} \begin{pmatrix} \hat{a}_k^{(l-1)} \\ \hat{b}_k^{(l-1)} \end{pmatrix} \times U_k \begin{pmatrix} \hat{a}_k^{(l-1)} \\ \hat{b}_k^{(l-1)} \end{pmatrix},$$

where

$$\begin{aligned} A_k(a, b) &= -n_k^{-1/2} \frac{\partial U_k(a, b)}{\partial(a, b)} \\ &= \frac{1}{n_k} \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} p_{kij}(a, b) q_{kij}(a, b) \begin{pmatrix} 1 & t_{kij} \\ t_{kij} & t_{kij}^2 \end{pmatrix} \end{aligned}$$

$$p_{kij}(a, b) = g^{-1}(a + bt_{kij}) = \frac{e^{a+bt_{kij}}}{1 + e^{a+bt_{kij}}} \quad (1)$$

and $q_{kij}(a, b) = 1 - p_{kij}(a, b)$.

According to Liang and Zeger,^[6] for large n , $\sqrt{n_k}(\hat{a}_k - a_k, \hat{b}_k - b_k)^T$ is asymptotically normal, with mean 0 and variance V_k that can be consistently estimated by

$$\hat{V}_k = A_k^{-1}(\hat{a}_k, \hat{b}_k) \hat{\Sigma}_k A_k^{-1}(\hat{a}_k, \hat{b}_k)$$

where

$$\hat{\Sigma}_k = \frac{1}{n_k} \sum_{i=1}^{n_k} \left\{ \sum_{j=1}^{m_{ki}} \hat{\varepsilon}_{kij} \begin{pmatrix} 1 \\ t_{kij} \end{pmatrix} \right\}^{\otimes 2},$$

$\hat{\varepsilon}_{kij} = y_{kij} - p_{kij}(\hat{a}_k, \hat{b}_k)$, and $c^{\otimes 2} = cc^T$ for a vector c . Let $\hat{v}_k$ be the (2,2) component of $\hat{V}_k$.

SAMPLE SIZE CALCULATION

Suppose that we want to test on the rate of change between two groups, i.e. $H_0: b_1 = b_2$. Based on the asymptotic results from the previous section, we can reject $H_0: b_1 = b_2$, in favor of $H_1: b_1 \neq b_2$ when

$$\left| \frac{\hat{b}_1 - \hat{b}_2}{\sqrt{\hat{v}_1/n_1 + \hat{v}_2/n_2}} \right| > z_{1-\alpha/2}, \quad (2)$$

where $z_{1-\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of a standard normal distribution.

In this section, we derive a sample size formula for the two-sided test^[2] to detect $H_1: |b_2 - b_1| = d(>0)$ with power $1 - \beta$. When designing a study, we usually schedule fixed visit times $t_1 < \dots < t_m$ for m repeated measurements from each subject. We often set $t_1 = 0$ for the baseline measurement time. When the study is conducted, however, the subjects may skip some visit times due to various causes, which results in missing values, or may not follow the visit schedule correctly so that the observed visit times may be variable. Jung and Ahn^[3] show, through simulations

in continuous outcome variable cases, that the sample size formula based on fixed measurement times is very accurate, even when the observed measurement times are widely distributed around the scheduled times.

By simple algebra, we can derive a sample size formula to detect the specified difference $|b_2 - b_1| = d$ with power $1 - \beta$,

$$n = \frac{(z_{1-\alpha/2} + z_{1-\beta})^2 (v_1/r_1 + v_2/r_2)}{d^2}, \quad (3)$$

where $v_k = \lim_{n \rightarrow \infty} \hat{v}_k$. The expression of v_k is slightly different between continuous and binary outcome variable cases, as shown in the following subsections.

In order to allow for missing, let δ_j denote the proportion of patients with observation at t_j and $\delta_{jj'}$ and the proportion of patients with observations at both t_j and $t_{j'}$. Also, let $\rho_{jj'} = \text{corr}(y_{kij}, y_{kj'})$. We assume that the missing pattern and correlation structure are common in two treatment groups. "Modeling Missing Pattern and Correlation Structure" discusses specific models for missing pattern and correlation structure.

Continuous Outcome Variable Case

We assume that the continuous outcome variable has a constant variance $\text{var}(y_{kij}) = \sigma^2$ over time, which is common between two treatment groups. Jung and Ahn^[3] show that $v_1 = v_2 = v$ is expressed as

$$v = \frac{\sigma^2(s^2 + c)}{s^4},$$

where

$$s^2 = \sum_{j=1}^m \delta_j (t_j - \tau)^2$$

$$c = \sum_{j \neq j'} \delta_{jj'} \rho_{jj'} (t_j - \tau)(t_{j'} - \tau)$$

and

$$\tau = \frac{\sum_{j=1}^m \delta_j t_j}{\sum_{j=1}^m \delta_j}.$$

Hence, Eq. 3 is simplified to

$$n = \frac{v(z_{1-\alpha/2} + z_{1-\beta})^2}{d^2 r_1 r_2}. \quad (4)$$

Note that we do not have to specify the true values for $\{(a_k, b_k), k = 1, 2\}$, but only the difference $|b_2 - b_1| = d$ in

sample size calculation. The sample size is proportional to the variance of measurement error σ^2 , and decreases as r_1 approaches 1/2.

Chow et al.^[1] propose a sample size formula for ANOVA with repeated measures. Their formula is similar to the formula for K-sample by Jung and Ahn^[4] under compounding symmetry (CS) and no missing.

Binary Outcome Variable Case

Let $p_{kj} = a_k + b_k t_k$ denote the success probabilities under H_1 . Jung and Ahn^[5] show that

$$v_k = \frac{s_k^2 + c_k}{s_k^4},$$

where

$$s_k^2 = \sum_{j=1}^m \delta_j p_{kj} q_{kj} (t_j - \tau_k)^2$$

$$c_k = \sum_{j \neq j'} \delta_{jj'} \rho_{jj'} \sqrt{p_{kj} q_{kj} p_{kj'} q_{kj'}} (t_j - \tau_k)(t_{j'} - \tau_k),$$

and

$$\tau_k = \frac{\sum_{j=1}^m \delta_j p_{kj} q_{kj} t_j}{\sum_{j=1}^m \delta_j p_{kj} q_{kj}}.$$

As shown here, the sample size formula under the binary outcome variable case depends on the probabilities $(p_{kj}, j = 1, \dots, m)$ under H_1 , so that we need to specify all regression parameters $\{(a_k, b_k), k = 1, 2\}$. Let $d = b_2 - b_1$ denote the difference in slope between two groups under H_1 . If there exist pilot data for the control group (group 1), then we may use the estimates as the parameter values, a_1 and b_1 . If $t_1 = 0$ is the time of randomization, the intercepts in the two groups are set the same, i.e. $a_1 = a_2$. By setting $b_2 = b_1 + d$, we can specify all regression coefficients under H_1 .

If there are no pilot data available, we may specify the binary probabilities at the baseline, p_{11} , and at the end of the follow-up, p_{1m} , for the control group. Then, we obtain (a_1, b_1) by

$$b_1 = \frac{g(p_{1m}) - g(p_{11})}{t_m - t_1}, \quad (5)$$

$$a_1 = g(p_{11}) - b_1 t_1 = g(p_{11}).$$

And we set $a_2 = a_1$ (since $p_{11} = p_{21}$ at the baseline) and $b_2 = b_1 + d$.

MODELING MISSING PATTERN AND CORRELATION STRUCTURE

The calculation of n (or v_k) requires projection of the missing probabilities and the true correlation structure.

Missing Pattern

In order to specify $\delta_{jj'}$, we need to estimate the missing pattern. If missing at time t_j is independent of missing at time $t_{j'}$ for each patient, then we have $\delta_{jj'} = \delta_j \delta_{j'}$ and call this type *independent missing*.

In some studies, subjects missing at a measurement time may be missing at all following measurement times, as in the labor pain study discussed in the Introduction. This type of missing is called *monotone missing*. In this case, we have $\delta_{jj'} = \delta_{j'}$ for $j < j'$ ($\delta_1 \geq \dots \geq \delta_m$). In the monotone missing case, one may want to specify the proportion of patients who will contribute exactly the first j observations, say η_j . Then, noting that $\eta_j = \delta_j - \delta_{j+1}$ for $j = 1, \dots, m-1$ and $\eta_m = \delta_m$, we can obtain δ_j recursively starting from δ_m . Note also that $\sum_j \eta_j = \delta_1$, which equals 1 if all patients have measurements at the first measurement time t_1 .

In summary, we consider two missing patterns as candidates to the true one: (a) independent missing, where $\delta_{jj'} = \delta_j \delta_{j'}$ and (b) monotone missing, where $\delta_{jj'} = \delta_{j'}$ for $j < j'$ ($\delta_1 \geq \dots \geq \delta_m$).

Correlation Structure

Now, we specify the “true” correlation structure $\rho_{jj'}$. In the continuous outcome case, a reasonable model for $\varepsilon_{ij} = y_{ij} - g^{-1}(a + bt_{ij})$ may be

$$\varepsilon_{ij} = u_i + e_{ij},$$

where u_i are subject-specific error terms when variance σ_u^2 and e_{ij} are serially correlated, within-subject error terms with variance σ_e^2 and correlation coefficients $\tilde{\rho}_{jj'}$. Assuming that u_i and e_{ij} are independent, we have

$$\text{cov}(\varepsilon_{ij}, \varepsilon_{ij'}) = \sigma_u^2 + \sigma_e^2 \tilde{\rho}_{jj'}.$$

Often, the variation between subjects (σ_u^2) is much larger than that within subject (σ_e^2). In this case, we have

$$\text{cov}(\varepsilon_{ij}, \varepsilon_{ij'}) \approx \sigma_u^2$$

and a CS correlation structure, $\rho_{jj'} = \rho$ for $j \neq j'$, that may be a reasonable approximation to the true one.

On the other hand, if the variation within subject (σ_e^2) dominates over the variation between subjects (σ_u^2), then we will have

$$\text{cov}(\varepsilon_{ij}, \varepsilon_{ij'}) \approx \sigma_e^2 \tilde{\rho}_{jj'},$$

so that a serial correlation structure may be a reasonable approximation to the true one. One of the most popular serial correlation structures, especially when measurement times are not equidistant, is a continuous autocorrelation model with order 1, AR(1), for which $\rho_{jj'} = \rho^{|t_j - t_{j'}|}$. We can make similar arguments in “discrete outcome case.”

We consider two correlation structures as candidate approximations to the true one: (i) CS, where $\rho_{jj'} = \rho$ and (ii) AR(1), where $\rho_{jj'} = \rho^{|t_j - t_{j'}|}$.

EXAMPLES

For sample size calculation, the following parameters need to be specified commonly in both continuous and discrete outcome variable cases.

- Type I and II errors α and β , respectively.
- Clinically significant difference, $|b_2 - b_1| = d$.
- Allocation proportion for group k , r_k .
- Correlation structure and the associated correlation parameter ρ , i.e. (i) $\rho_{jj'} = \rho$ for CS or (ii) $\rho_{jj'} = \rho^{|t_j - t_{j'}|}$ for AR(1).
- Proportion of patients with an observation at t_j , δ_j .
- Missing pattern: (a) independent missing ($\delta_{jj'} = \delta_j \delta_{j'}$) or (b) monotone missing ($\delta_{jj'} = \delta_{j'}$ for $j < j'$).

In addition, we need to specify $\sigma^2 = \text{var}(\varepsilon_{ij})$ in the continuous outcome variable case, and the regression coefficients $\{(a_k, b_k), k = 1, 2\}$ under H_1 in the binary outcome variable case.

We demonstrate our sample size formula with real longitudinal studies.

Labor Pain Study (Continuous Outcome Case)

Suppose that we want to design a new study on labor pain based on the data reported by Davis.^[2] The original study was briefly discussed in the Introduction. As in the original study, we assume monotone missing. In this study, the measurement times were equispaced, so that we set $t_j = j-1$ ($j = 1, \dots, 6$) for convenience. From the data, we obtained $\sigma^2 = 815.84$. Suppose we want to detect a difference of σ in mean pain score between two groups at t_6 . So, we project $d = \sigma/(t_6 - t_1) = 5.71$ in a new study. We consider a balanced randomization, i.e., $r_1 = r_2 = 1/2$. Also, from the data, the proportion of observed measurements are

$$(\delta_1, \delta_2, \delta_3, \delta_4, \delta_5, \delta_6) = (1, 0.90, 0.78, 0.67, 0.54, 0.41).$$

From these results, we obtain $\tau = 2.02$ and $s^2 = 11.42$.

Suppose that we want to detect a difference of $d = 5.71$ with 80% of power ($z_{1-\beta} = 0.84$) using a two-sided $\alpha = 0.05$ ($z_{1-\alpha/2} = 1.96$) test. Under CS, we obtain $\rho = 0.64$ and $c = -3.13$ from the data, so that we have $v = 815.84 \times (11.42 - 3.13)/11.42^2 = 0.0635$.

Hence, from Eq. 4, the required sample size is calculated as

$$n = \left\lceil \frac{0.0635 \times (1.96 + 0.84)^2}{5.71^2} \right\rceil + 1 = 50$$

where $\lceil x \rceil$ is the largest integer not exceeding x .

Under AR(1), we obtain from the data $\rho = 0.80$ and $c = 2.31$, so that the required sample size for detecting $d = 5.71$ with 80% of power using a two-sided $\alpha = 0.05$ test is given as $n = 83$. The sample size under AR(1) is larger than that under CS, by about 66%, in this example.

GENISOS (Binary Outcome Case)

As stated in the Introduction, GENISOS is an observational study. Suppose that we want to develop a new clinical trial to examine the effect of a new drug in preventing the occurrence of pulmonary fibrosis in subjects with scleroderma based on the observations from the observational study. The parameter values specified below for the sample size calculation are approximated by the estimates from the current data set of GENISOS.

We want to estimate the sample size for the new clinical trial using $\alpha = 0.05$ and $1 - \beta = 0.8$. As in GENISOS, the presence or absence of pulmonary fibrosis will be assessed at the baseline, and at months 6, 12, 18, 24, and 30. Since the measurement times are equidistant, we set $t_j = j-1$ ($j = 1, \dots, 6$) for the $m = 6$ time points. The within-group correlation structure of the repeated measurements conforms to AR(1) with the adjacent correlation equal to $\rho = 0.8$, that is, $\rho_{jj'} = 0.8^{|j-j'|}$. We consider assigning an equal number of scleroderma patients in each of two groups, i.e., $r_1 = r_2 = 1/2$.

Approximately 75% of scleroderma patients do not have pulmonary fibrosis at the baseline in the ongoing GENISOS. We project that the proportion of subjects without pulmonary fibrosis is 75% at the baseline, i.e., $p_{1,1} = 0.75$ and 50% at 30 months, i.e., $p_{1,6} = 0.50$, in a placebo group. We assume that a new therapy will prevent or delay further occurrence of pulmonary fibrosis. That is, the proportion of subjects without pulmonary fibrosis will remain 75% during a 30-month study in a new therapy group, i.e., $p_{2,1} = p_{2,6} = 0.75$. From these values and Eq. 5, we obtain

$$b_1 = \frac{g(0.5) - g(0.75)}{5 - 0} = -0.220,$$

and $a_1 = g(0.75) = 1.099$. Similarly, we obtain $(a_2, b_2) = (1.099, 0)$, so that $d = 0 - (-0.220) = 0.220$. By Eq. 1, the probabilities of no pulmonary fibrosis at the 6 time points

are obtained as (0.750, 0.707, 0.659, 0.608, 0.555, 0.500) for the placebo group, and (0.750, 0.750, 0.750, 0.750, 0.750, 0.750) for the treatment group.

The proportions of observed measurements are expected to be

$$(\delta_1, \delta_2, \delta_3, \delta_4, \delta_5, \delta_6) = (1, 0.95, 0.90, 0.85, 0.80, 0.75).$$

Suppose that we expect independent missing. Then, we obtain $\delta_{jj'}$ from the specified δ_j values using $\delta_{jj'} = \delta_j \delta_{j'}$. Now we have all the parameter values required, and obtain $v_1 = 0.305$ and $v_2 = 0.353$. Finally, from Eq. 3, we obtain

$$n = \left\lceil \frac{(1.96 + 0.84)^2 (0.305/0.5 + 0.353/0.5)}{0.220^2} \right\rceil + 1 = 215.$$

If we assume monotone missing ($\delta_{jj'} = \delta_{j \vee j'}$), we obtain $v_1 = 0.324$, $v_2 = 0.308$, and $n = 229$.

Abstract

To speed up drug development to allow faster access to medicines for patients globally, the design of multiregional clinical trials incorporates subjects from many countries around the world under the same protocol. The aim of a multiregional clinical trial is to show the efficacy of a drug in various global regions, and concurrently to evaluate the possibility of applying the overall trial results to each region so that simultaneous drug development, submission, and approval in the world are possible. In this entry, we reviewed some recent developments for sample size determination for MRCT. In the first part, we reviewed the methods for sample size calculation based on the assumptions that the effect size is uniform across regions and treatment effect is heterogeneous across regions respectively. In the second part, we reviewed statistical criteria for assessing the consistency between the region of interest and overall results.

Keywords: Bridging study; Consistent Trend; Ethnic effect; Multi-regional clinical trials.

1 INTRODUCTION

Biotechnology has been identified as one of the key technologies in the 21st century. Especially, biopharmaceutical industry is the most vital and important industry. In recent years, many pharmaceutical companies and regulatory agencies have spent efforts to promote global drug development and international clinical study. The aim of a MRCT is to show the efficacy of a drug in various global regions, and concurrently to evaluate the possibility of applying the overall trial results to each region. Doing so may enable simultaneous drug development, submission, and approval in the world so that the drug lag or the time lag for drug approval can be shortened in key markets.

Recently, the Japanese Ministry of Health, Labour and Welfare (MHLW) published the “Basic Principles on Global Clinical Trials” (1) guidance to promote Japan’s participation in global drug development. By Japanese guidance, global clinical studies refer to studies planned with the objective of world-scale development and approval of new drugs in which study sites of a multiple number of countries and regions participate in a single study based on a common protocol and conducted at the same time in parallel. The ICH E5 11th Q&A (2) also discusses the concept of a MRCT and states that “It may be desirable in certain situations to achieve the goal of bridging by conducting a multi-regional trial under a common protocol that includes sufficient numbers of patients from each of

multiple regions to reach a conclusion about the effect of the drug in all regions...” In 2016, the ICH released the draft guidance E17 of MRCT entitled “General Principles for Planning and Design of Multi-Regional Clinical Trials.” (3) The purpose of E17 is to describe general principles for the planning and design of MRCTs with the aim of increasing the acceptability of MRCTs in global regulatory submissions. All guidelines provide a framework on how to demonstrate the efficacy of a drug in all participating regions while also evaluating the possibility of applying the overall trial results to each region in a MRCT. Some practical issues that are commonly encountered when conducting multiregional clinical trials including criteria for assessment of similarity between regions and sample size calculation/allocation are also discussed in the review article by Chow and Hsiao (4).

When planning MRCTs, the differences in race, diet, environment, culture, and medical practice among regions may have an impact, and should be identified during the planning stage. In the first part of this entry, we will review some recent developments for sample size determination for MRCT. Another important issue is to evaluate the possibility of applying the overall trial results in a MRCT to each region. The Japanese guidance has provided two methods as examples for establishing consistency in treatment effect between the Japanese group and the entire group. In the second part of this entry, we will review statistical criteria for assessing the consistency between the region of interest and overall results.

2 SAMPLE SIZE FOR MRCT

Assume that the MRCT is conducted to compare a test product and a placebo control on a continuous efficacy endpoint. Let M be the number of regions.

2.1 Effect size is uniform across regions

Let X_{ij} and Y_{ik} be the efficacy responses for the j^{th} subject and the k^{th} subject in the i^{th} region receiving the test product and the placebo control respectively, $i = 1, \dots, M$, $j = 1, \dots, n_i^T$, and $k = 1, \dots, n_i^C$. Assume that $X_{ij} \sim N(\mu^T, \sigma^2)$ and $Y_{ik} \sim N(\mu^C, \sigma^2)$, where $N(\mu, \zeta^2)$ represents a normal distribution with mean μ and variance ζ^2 . Here a higher value of the population mean represents a better outcome. For convention, we assume that σ^2 is known, although in actual practice, σ^2 is unknown and must be estimated from some data. Let $\Delta = \mu^T - \mu^C$. It is assumed that effect size (Δ/σ) is uniform across regions. The hypothesis of testing for the overall treatment effect is given as

$$H_0: \Delta \leq 0 \text{ vs. } H_A: \Delta > 0. \quad (1)$$

Although the hypothesis is one-sided, the method proposed below can be straightforwardly extended to the two-sided hypothesis. Let Z the test statistic for (1). It can be derived that

$$Z = \frac{\left(\sum_{i=1}^M \sum_{j=1}^{n_i^T} X_{ij} \right) / \sum_{i=1}^M n_i^T - \left(\sum_{i=1}^M \sum_{k=1}^{n_i^C} Y_{ik} \right) / \sum_{i=1}^M n_i^C}{\sigma \sqrt{\frac{1}{\sum_{i=1}^M n_i^T} + \frac{1}{\sum_{i=1}^M n_i^C}}}.$$

Let N denote the total sample size for each group planned for detecting an expected treatment difference $\Delta = \delta$ at the desired significance level α and with power $1 - \beta$. Thus,

$$N = \frac{2(z_{1-\alpha} + z_{1-\beta})^2 \sigma^2}{\delta^2},$$

where $z_{1-\alpha}$ is the $(1 - \alpha)^{\text{th}}$ percentile of the standard normal distribution (5, 6). For example, by considering $\alpha = 0.025$, $\beta = 0.1$, $\delta = 6$, and $\sigma = 14$, the sample size required for each group is 115.

2.2 Heterogeneous treatment effect across regions

Since the design of MRCTs incorporates subjects from many countries around the world, it might be reasonable to anticipate heterogeneity in treatment effect due to ethnic differences. In this section, much of the notation

developed in Section 2.1 will continue to be used. Different from Section 2.1, here we assume that $X_{ij} \sim N(\mu_i^T, \sigma_i^2)$ and $Y_{ik} \sim N(\mu_i^C, \sigma_i^2)$. Let θ_i be the treatment difference in the i^{th} region. That is, $\theta_i = \mu_i^T - \mu_i^C$. To address the heterogeneous treatment effect across regions, θ_i is considered as a random effect. More specifically, Chen et al. (7) assumed that $\theta_i \sim N(\theta, \tau^2)$, $i = 1, \dots, M$. Here θ can be thought of as the overall treatment effect for the MRCT. The hypothesis of testing for the overall treatment effect in the MRCT can thus be given as

$$H_0: \theta \leq 0 \text{ vs. } H_A: \theta > 0. \quad (2)$$

Let $\hat{\theta}_i$ represent the estimator of θ_i . It leads to $\hat{\theta}_i = \bar{X}_i - \bar{Y}_i$, where $\bar{X}_i = \left(\sum_{j=1}^{n_i^T} X_{ij} \right) / n_i^T$ and $\bar{Y}_i = \left(\sum_{k=1}^{n_i^C} Y_{ik} \right) / n_i^C$. Consequently, the general random effect model can be given by

$$\hat{\theta}_i = \theta + \nu_i + \varepsilon_i,$$

where $\nu_i \sim N(0, \tau^2)$, $\varepsilon_i \sim N(0, \xi_i^2)$, and ν_i and ε_i are assumed to be independent. It follows that $\hat{\theta}_i \sim N(\theta, \xi_i^2 + \tau^2)$ where

$$\xi_i^2 = \frac{\sigma_i^2}{n_i^T} + \frac{\sigma_i^2}{n_i^C} = \sigma_i^2 \left(\frac{1}{n_i^T} + \frac{1}{n_i^C} \right).$$

Let $\hat{\sigma}_i^2$, $\hat{\tau}^2$, and $\hat{\xi}_i^2$ be the estimators of σ_i^2 , τ^2 , and ξ_i^2 respectively. We obtain that

$$\hat{\sigma}_i^2 = \frac{(n_i^T - 1)s_{iX}^2 + (n_i^C - 1)s_{iY}^2}{n_i^T + n_i^C - 2} \text{ and } \hat{\xi}_i^2 = \hat{\sigma}_i^2 \left(\frac{1}{n_i^T} + \frac{1}{n_i^C} \right),$$

where $s_{iX}^2 = \sum_{j=1}^{n_i^T} (X_{ij} - \bar{X}_i)^2 / (n_i^T - 1)$ and $s_{iY}^2 = \sum_{k=1}^{n_i^C} (Y_{ik} - \bar{Y}_i)^2 / (n_i^C - 1)$. Set $w_i^{-1} = \xi_i^2$ and let $\hat{w}_i$ be the estimator of w_i . By DerSimonian and Laird (8), the method of moments estimator $\hat{\tau}^2$ for τ^2 is given by

$$\hat{\tau}^2 = \frac{\hat{w}}{\hat{w}^2 - \sum_{i=1}^M \hat{w}_i^2} \left\{ \sum_{i=1}^M \hat{w}_i \left(\hat{\theta}_i - \sum_{i=1}^M \frac{\hat{w}_i \hat{\theta}_i}{\hat{w}} \right)^2 - (M - 1) \right\},$$

where $\hat{w} = \sum_{i=1}^M \hat{w}_i$. Note that the estimate $\hat{\tau}^2$ will be set to 0 if a negative estimate for τ^2 is derived. With use of the distributional assumption, we can obtain

$$\hat{\theta}_i \sim N(\theta, w_i^{-1} + \tau^2).$$

Set $w_i^* = (w_i^{-1} + \tau^2)^{-1}$. Let $\hat{w}_i^*$ be the estimate of w_i^* . Consequently,

$$\hat{w}_i^* = (\hat{w}_i^{-1} + \hat{\tau}^2)^{-1}.$$

Note that the maximum likelihood estimate of θ is given by $\hat{\theta}^*$, where

$$\hat{\theta}^* = \sum_{i=1}^M \hat{\theta}_i w_i^* / \sum_{i=1}^M w_i^*,$$

by treating the term w_i^{*-1} as if it were the true variance of $\hat{\theta}_i$. It can be seen that $\hat{\theta}^*$ is asymptotically unbiased for θ , with variance approximately equal to $1 / \sum_{i=1}^M \hat{w}_i^*$. Let $S = \left[\sum_{i=1}^M \hat{w}_i^* (\hat{\theta}_i - \hat{\theta}^*)^2 \right] / \left(\sum_{i=1}^M \hat{w}_i^* \right)$. Since the number of regions, M , should be small, by Hartung (9), $\left(\sum_{i=1}^M \hat{w}_i^* \right) S$ can be approximated by a (central) χ^2 -distribution with $(M-1)$ degrees of freedom and $\hat{\theta}^*$ and S are stochastically independent. Consequently, the test statistic for (2) under H_0 is given as

$$T = \frac{\hat{\theta}^* \sqrt{\sum_{i=1}^M \hat{w}_i^*}}{\sqrt{\left(\sum_{i=1}^M \hat{w}_i^* \right) S / (M-1)}} = \frac{\hat{\theta}^*}{\sqrt{S / (M-1)}} \sim t_{M-1}, \quad (3)$$

where t_n represents the t distribution with degrees of freedom n .

Under the alternative hypothesis that $\theta = \Delta$, the test statistic T in (3) has a noncentral t distribution with $(M-1)$ degrees of freedom and noncentrality parameter $\sqrt{(M-1) \sum_{i=1}^M w_i^* \Delta}$. Let N be the total sample size required per group planned for detecting an expected treatment difference $\theta = \Delta$ at the desired significance level α and with power $1 - \beta$ for the MRCT, and p_i denote the proportion of patients out of $2N$ in the i^{th} region, $i = 1, \dots, M$, where $\sum p_i = 1$. Consequently, given σ_i^2 and τ^2 , N needs to satisfy

$$\begin{aligned} 1 - \beta &= P(T > t_{1-\alpha, M-1} \mid \theta = \Delta) \\ &= 1 - F_{M-1} \left(t_{1-\alpha, M-1} \mid \sqrt{(M-1) \left(\sum_{i=1}^M w_i^* \right) \Delta} \right) \\ &= 1 - F_{M-1} \left(t_{1-\alpha, M-1} \mid \Delta \sqrt{(M-1) \sum_{i=1}^M \left(\frac{2\sigma_i^2}{p_i N} + \tau^2 \right)} \right), \end{aligned} \quad (4)$$

where $t_{1-\alpha, n}$ denotes the upper α_{th} percentile of the t distribution with degrees of freedom n , and $F_{M-1}(\cdot \mid \delta)$ is the cumulative distribution function of the noncentral t -distribution with $(M-1)$ degrees of freedom and noncentral parameter δ . If $\sigma_i^2 = \sigma^2$, the equation (4) reduces to

$$\beta = F_{M-1} \left(t_{\alpha, M-1} \mid \Delta \sqrt{(M-1) \sum_{i=1}^M \left(\frac{2\sigma^2}{p_i N} + \tau^2 \right)} \right),$$

Given τ^2 , σ^2 , p_i and Δ , N can thus be derived by the above equation with specification of α and β .

Another alternative approach is proposed by Hung et al. (10). They derive that

$$\hat{\theta}_i \mid \theta_i \sim N(\theta_i, \xi_i).$$

If θ is interpretable for each region, we can estimate θ by $\hat{\theta}$, where

$$\hat{\theta} = \sum_{i=1}^M p_i \hat{\theta}_i.$$

It follows that

$$E(\hat{\theta}) = \theta$$

and

$$\text{Var}(\hat{\theta}) = 2\sigma^2 \left[\frac{1}{N} + \left(\frac{\tau}{2\sigma} \right)^2 \sum_{i=1}^M p_i^2 \right],$$

Where $\sigma_i^2 = \sigma^2$, $i = 1, \dots, M$. Let N^* be the total sample size required per group planned for detecting an expected treatment difference $\theta = \Delta$ at the desired significance level α and with power $1 - \beta$ for the MRCT. Assuming $\tau^2 \neq 0$, we can thus derive that

$$N^* = \left[\left(\frac{\Delta}{2\sigma(z_\alpha + z_\beta)} \right) - \left(\frac{\tau}{2\sigma} \right)^2 \sum_{i=1}^M p_i^2 \right]^{-1}.$$

By considering $\alpha = 0.025$, $\beta = 0.2$, $M = 3$, $\Delta = 13$, and $\sigma = 20$, Tables 1 and 2 exhibit the total sample size required

Table 1 The Sample Sizes of N and N^* when $\Delta = 13$, $\tau^2 = 1$, $\sigma = 20$

3 CONSISTENCY CRITERIA IN MRCT

When planning a MRCT, the definitions of all regions are very critical (11). In ICH E5, the ethnic factors are classified into two categories: intrinsic and extrinsic factors. Intrinsic ethnic factors are more genetic and physiologic in nature (e.g., genetic polymorphism, age, gender, etc.) that can define and recognize the population in each region and perhaps influence the ability to extrapolate clinical data between regions. On the contrary, extrinsic ethnic factors are more social and cultural in nature (e.g., medical practice, diet and practices in clinical trials and conduct) which are associated with the environment and culture. Most importantly, ICH E17 suggests that “ethnic factors are a major point of consideration when planning MRCTs and should be identified during the planning stage, and information about them should also be collected and evaluated when conducting MRCTs.” Here region may refer to a geographical region, country or regulatory region in MRCT. ICH E17 also suggests that some regions may be pooled at the design stage.

In a MRCT, after showing the overall efficacy of a drug in all global regions, we can simultaneously evaluate the possibility of applying the overall trial results to each region and consequently support registration in each region. Therefore, how to bridge the results of the MRCT to each region is another important issue. In this regard,

ICH E17 has provided some approaches. Briefly, the first approach is to show that similar trends in treatment effects across regions can be demonstrated. The second approach is to show that the region-specific treatment effect preserves some pre-specified proportion of the overall treatment effect. The third approach is to show that significant results within one or more regions can be achieved. Similar to the second approach suggested by ICH E17, the Japanese MHLW guidance (1) has provided two methods as examples for deciding on the number of Japanese subjects in a MRCT for establishing the consistency of treatment effects between the Japanese group and the entire group.

For Method 1, it is suggested that given that the overall result is significant at α level, we will judge whether the treatment is effective in the specific region by the following criterion:

$$D_s \geq \rho D_{All}, \quad (5)$$

for some pre-specified $0 < \rho < 1$, where D_s and D_{All} are the treatment effects for the specific region and the entire group, respectively. Selection of the magnitude, ρ , of consistency trend may be critical. All differences in ethnic factors between the specific region and other regions should be taken into account. The Japanese MHLW suggests that ρ be 0.5 or greater. However, the determination of ρ will be and should be different from product to product, and from therapeutic area to therapeutic area. The design of such a study involves determination of sample size for the specific region to achieve the required power for the consistency assessment. That is, the selected sample size should satisfy

$$P(D_s/D_{All} > \pi) > \gamma.$$

Here γ should be selected to be 0.8 or greater. Other statistical criteria for consistency between the specific region and overall results can also be found in Uesaka (12) and Ko et al. (5), and are shown as follows.

- $D_s \geq \rho D_{sc}$ for some $0 < \rho < 1$,
- $D_s \geq \rho D_{All}$ for some $0 < \rho < 1$,
- $\rho \leq D_s/D_{sc} \leq 1/\rho$, for some $0 < \rho < 1$,
- $\rho \leq D_s/D_{All} \leq 1/\rho$, for some $0 < \rho < 1$,

where D_{sc} be the observed mean difference from regions other than the specific region. Note that the consistency criterion (ii) is equivalent to (5). These consistency criteria can be thought of as that the estimate of treatment effect from the specific region is noninferior/equivalent to the estimate of treatment effect from overall or from regions other than the specific region.

Let p_s denote the proportion of patients out of the overall sample size in the specific region. For convention, by considering the assumption in Section 2.1 that the effect size (Δ/σ) is uniform across regions, we now describe the method of determination of p_s to ensure that the assurance

probabilities of criteria (i)–(iv) given $\Delta = \delta$ are maintained at a desired level, say 80%.

The assurance probability of criterion (i) given $\Delta = \delta$ can be expressed as

$$AP_1 = P_\delta(D_s > \rho D_{sc} | Z > Z_{1-\alpha}) \\ = \left[\int_{a_1}^{\infty} \left(\Phi\left(\frac{u-c_2}{c_1}\right) - \Phi\left(\frac{c_5-c_3u}{c_4}\right) \right) \varphi(u) du \right] / (1-\beta),$$

where P_δ is the probability measure with respect to $\Delta = \delta$,

$$c_1 = \rho \sqrt{\frac{p_s}{1-p_s}}, \quad c_2 = (\rho-1)\sqrt{p_s}(Z_{1-\alpha} + Z_{1-\beta}), \quad c_3 = \sqrt{p_s},$$

$$c_4 = \sqrt{1-p_s}, \quad c_5 = -Z_{1-\beta}, \quad \text{and} \quad a_1 = c_2 + \frac{c_1(c_5 - c_2c_3)}{c_1c_3 + c_4}.$$

Similarly, the assurance probabilities of criteria (ii), (iii), and (iv) can be represented by

$$AP_2 = P_\delta(D_s > \rho D_{All} | Z > Z_{1-\alpha}) \\ = \left[\int_{a_2}^{\infty} \left(\Phi\left(\frac{u-c_7}{c_6}\right) - \Phi\left(\frac{c_5-c_3u}{c_4}\right) \right) \varphi(u) du \right] / (1-\beta),$$

$$\text{where } c_6 = \frac{\rho\sqrt{p_s(1-p_s)}}{1-\rho p_s}, \quad c_7 = \frac{(\rho-1)\sqrt{p_s}}{1-\rho p_s}(Z_{1-\alpha} + Z_{1-\beta}),$$

$$\text{and } a_2 = c_7 + \frac{c_6(c_5 - c_7c_3)}{c_6c_3 + c_4};$$

$$AP_3 = P_\delta\left(\rho < \frac{D_s}{D_{sc}} < \frac{1}{\rho} | Z > Z_{1-\alpha}\right) \\ = AP_1 - \left[\int_{a_3}^{\infty} \left(\Phi\left(\frac{u-c_9}{c_8}\right) - \Phi\left(\frac{c_5-c_3u}{c_4}\right) \right) \varphi(u) du \right] / (1-\beta),$$

$$\text{where } c_8 = \frac{1}{\rho} \sqrt{\frac{p_s}{1-p_s}}, \quad c_9 = \left(\frac{1}{\rho} - 1\right)\sqrt{p_s}(Z_{1-\alpha} + Z_{1-\beta}), \quad \text{and}$$

$$a_3 = c_9 + \frac{c_8(c_5 - c_9c_3)}{c_8c_3 + c_4};$$

$$AP_4 = P_\delta\left(\rho < \frac{D_s}{D_{All}} < \frac{1}{\rho} | Z > Z_{1-\alpha}\right) \\ = P_\delta\left(\rho < \frac{D_s}{D_{All}} | Z > Z_{1-\alpha}\right) - P_\delta\left(\frac{1}{\rho} \leq \frac{D_s}{D_{All}} | Z > Z_{1-\alpha}\right) \\ = P_\delta(D_s > \rho D_{All} | Z > Z_{1-\alpha}) - P_\delta\left(D_s > \frac{1}{\rho} D_{All} | Z > Z_{1-\alpha}\right) \\ = AP_2 - P_\delta\left(D_s > \frac{1}{\rho} D_{All} | Z > Z_{1-\alpha}\right).$$

Given $\alpha = 0.025$, $\beta = 0.1$, and $\rho = 0.5$, Table 3 exhibits the assurance probabilities of criteria (i), (ii), (iii), and (iv) respectively for various values of p_s . It can be seen from

Table 3 The Assurance Probability for Observing Criteria (i), (ii), (iii), and (iv) given $\alpha = 0.025$, $\beta = 0.1$, and $\rho = 0.50$

p_s	AP_1	AP_2	AP_3	AP_4
0.10	0.71	0.72	0.52	0.58
0.15	0.74	0.76	0.59	0.68
0.20	0.78	0.80	0.64	0.75
0.25	0.80	0.83	0.67	0.80
0.30	0.82	0.86	0.70	0.84
0.35	0.83	0.89	0.71	0.87
0.40	0.85	0.91	0.72	0.90
0.45	0.86	0.93	0.73	0.92
0.50	0.86	0.94	0.73	0.94
0.55	0.87	0.96	0.73	0.96
0.60	0.88	0.97	0.72	0.97
0.65	0.88	0.98	0.71	0.98
0.70	0.88	0.99	0.69	0.99
0.75	0.87	0.99	0.67	0.99
0.80	0.86	1.00	0.64	1.00

Table 2 that the assurance probabilities of criterion (iii) will never reach 80% regardless of the value of p_s . However, the sample sizes for the first region have to be around 25% out of the total sample size respectively to ensure the assurance probabilities of criteria (i), (ii) and (iv) to be at least 80%.

Alternatively, based on the consistency criterion (7), Quan et al. (13) derived closed form formulas for the sample size calculation for the specific region for normal, binary and survival endpoints. For example, if we choose $\rho = 0.5$, $\gamma = 0.2$, $\alpha = 0.025$, and $\beta = 0.9$, then the Asian sample size has to be at least 22.4% of the overall sample size for the MRCT.

On the other hand, suppose there are three regions participated in the MRCT. For Method 2, the sample size should be set so that

$$P(D_1 > 0, D_2 > 0, D_3 > 0) > \gamma,$$

where D_i represents the observed treatment effect for region i , $i = 1, \dots, 3$. Again, γ should be chosen to be 0.8 or greater. Based on Method 2, Kawai et al. (4) proposed an approach to rationalize partitioning the total sample size among the regions so that a high probability of observing a consistent trend under the assumed treatment effect across regions can be derived, if the treatment effect is positive and uniform across regions in a MRCT.

4 CONCLUSION

A MRCT may incorporate subjects from many countries around the world under the same protocol. After showing the overall efficacy of a drug in all global regions, we

can simultaneously evaluate the possibility of applying the overall trial results to each region and consequently support registration in each region. In Asian countries, the trend for simultaneous clinical development being undertaken simultaneously with clinical trials conducted in Europe and the United States has been speedily rising. In particular, Taiwan, Korea, Hong-Kong, and Singapore have already had much experience in planning and conducting the MRCTs.

In this entry, we reviewed some recent developments for sample size determination for MRCT. In the first part, we reviewed the methods for sample size calculation based on the assumptions that the effect size is uniform across regions and treatment effect is heterogeneous across regions respectively. In the second part, we reviewed statistical criteria for assessing the consistency between the region of interest and overall results.

Sample Size Re-estimation Based on Observed Treatment Difference

Lu Cui

Aventis Pharmaceuticals, Inc., Bridgewater, Connecticut, U.S.A.

Abstract

This entry discusses statistical issues of sample size re-estimation as well as the benefits it presents to certain studies.

INTRODUCTION

Sample size re-estimation based on an interim treatment difference is an adaptive clinical trial strategy that allows modification of the initially projected total sample size based on an observed treatment difference at an interim stage of a clinical trial. Such an adaptive design has drawn much attention from clinical trial practitioners as a flexible alternative to the traditional fixed sample size design.

FIXED SAMPLE SIZE DESIGN

For a fixed sample size trial, the total sample size may be determined using the prior knowledge on the true treatment difference, the variability of the response variable, and the desired Type I and Type II error rates. Under the two-sample normal mean test setting, the dependency of the total sample size on the mentioned parameters is given by the equation

$$N = (Z_{\alpha} + Z_{\beta})^2 \sigma^2 / \Delta^2 \quad (1)$$

where Δ denotes the true treatment difference, σ denotes the standard deviation of the response variable, and α and β denote the desired Type I and Type II error rates, respectively. With the given error rates and known σ , the planned sample size for a clinical trial is obtained by replacing the unknown quantity Δ in Eq. 1 with its initial estimate, say δ . The accuracy of δ or its closeness to Δ , therefore, is crucially important for an accurate projection of the total sample size needed. Improperly chosen δ may result in an insufficient total sample size, potentially leading to the failure of the trial, or an overestimated sample size, unnecessarily increasing the cost and duration of the trial.

For fixed sample size clinical trials, the δ is primarily obtained based on previous trial data. There are, however, often situations in clinical trials where a reliable initial estimate of the true treatment difference is difficult or

impossible to obtain. For example, in clinical trials to study drugs in new classes or drugs for new indications in new patient populations, typically, little or no prior information on possible effect size of the drugs is available.

SAMPLE SIZE MODIFICATION BASED ON OBSERVED TREATMENT DIFFERENCE

The adaptive design allowing sample size re-estimation based on observed interim treatment difference is to target the situation where there is no available prior information to allow a reliable initial estimate of the true treatment difference and an accurate projection of the needed total number of patients is difficult to obtain if not impossible. Such a design is intended to provide the trial necessary flexibility to adjust the sample size in the midcourse of a clinical trial if the initially planned sample size is discovered improper.

For clinical trials in which the choice of δ may also be based on some other considerations, such as the clinically meaningful treatment difference (if it exists and is well defined), the constrain of available resource, the drug marketing strategy, etc., a minimum size of the treatment difference to be detected, denoted by $\delta_{\min}$, may be specified. In this case, a fixed sample size design with the total sample size projected based on $\delta = \delta_{\min}$ may be the choice because of its simplicity and efficiency. Even in this case, it might be wise to put a sample size adaptive plan into this chosen design just in case that the initially planned total sample size is significantly wrong. If no indication of an improper total sample size, the trial can go on according to the plan.

ISSUES ON SAMPLE SIZE MODIFICATION

Several issues need special attention when sample size re-estimation based on observed treatment difference is used.

Inflation of Type I Error Rate

It has been known that Type I error rate can be inflated when the total sample size is modified based on observed interim treatment difference but such an adaptation is not properly taken into account in the analysis.^[1–4] After the outcome-dependent sample size modification, the new total sample size is no longer a fixed but random quantity depending on the magnitude of the observed interim treatment difference. Consequently, if a traditional test statistic and critical value are used as if the sample size were fixed, the corresponding Type I error rate may not be at the target level. For example, if no interim testing is performed, with the sample size modification, the Type I error rate is $E(P(T > C|M))$ instead of usual $P(T > C)$ under the null hypothesis, where T and C are test statistic and critical value, respectively, and M is the new total random sample size. For a group sequential clinical trial,^[5] the Type I error rate calculation can be further complicated due to the change of information time scale after the change in total sample size.

Method for Projecting New Sample Size

A widely used method for sample size re-estimation based on observed treatment difference is the conditional power approach.^[6] To describe this approach, consider a two-arm clinical trial with one interim analysis performed at the interim time t . For testing whether or not the parameter of interest, say Δ , is zero, let T_1 and T_2 be the test statistics in the interim and the final analyses, respectively. Let Δ_1 be the interim estimate of Δ . The estimate Δ_1 is a function of T_1 . Let $CP(\Delta) = \Pr(T_2 > C_2 | T_1, \Delta)$, where C_2 is the critical value for the final analysis. The conditional power $CP(\Delta_1)$ is obtained by replacing the unknown Δ with its interim estimate Δ_1 in the formulation of the conditional probability $CP(\Delta)$. With the conditional power, a decision as to whether or not the sample size needs to be modified can be made. For example, the total sample size can be increased if the conditional power is less than a certain percent. Once this decision is made, the new total sample size per group, denoted by M , can be obtained by solving the equation

$$CP(\Delta_1) = 1 - \beta \quad (2)$$

where $1 - \beta$ is the level of conditional power to achieve. Note that M reduces to the original total sample size if there is no sample size change after the interim analysis.

Many factors such as magnitude of the observed treatment difference, policy for sample size re-estimation, and modifications of test statistic or critical value for controlling Type I error rate after sample size change may affect the value of the conditional power, consequently the projected new total sample size.

To illustrate the use of conditional power, consider the method suggested by Cui et al.^[3] With this method, the

final test statistic after the interim sample size change is modified to

$$U = W_1 T_1 + W_2 T^* \quad (3)$$

where T_1 and T^* are the standardized original test statistics constructed using the data collected before and after the interim analyses, respectively, and W_1 and W_2 are fixed weights. The corresponding conditional power can be written as

$$CP(\Delta_1) = \Pr[T^* > (C_2 - W_1 T_1)/W_2 | \Delta_1, T_1] \quad (4)$$

For normal mean test, T_1 and T^* are two independent standardized normal mean tests. For many often used large sample tests, T_1 and T^* are mutually independent and asymptotically normal with variance of 1.^[3] The conditional power (Eq. 4) can be easily calculated by treating T^* as the test statistic for the final analysis, Δ_1 as the true treatment difference, and $C^* = (C_2 - W_1 T_1)/W_2$ as the critical value for the final analysis. For example, for two sample normal mean test, the close form expression of the conditional power (Eq. 4) can be written as

$$CP(\Delta_1) = 1 - \Phi[C^* - T_1(M/n - 1)^{1/2}]$$

where T_1 is the Z-test statistic in the interim analysis, n is the interim sample size, and $\Phi(\cdot)$ is the standard normal distribution function. For two-sample proportion test, the conditional power has the same expression but T_1 is the standardized two-sample proportion test in the interim analysis. Similarly, conditional power can be calculated for logrank test using Eq. 4 in which T^* is the standardized difference of the values of Brownian motion process derived from the logrank test based on the subjects available before and after the interim analysis.^[3] Eqs. 4 and 2 imply that the additional number of subjects after the interim analysis can be projected for a specific level of the conditional power by treating T^* as the test statistic for the final analysis, Δ_1 as the true treatment difference, and $C^* = (C_2 - W_1 T_1)/W_2$ as the critical value for the analysis. It should be pointed out that in practice, the total sample size can never be increased unlimitedly, and therefore an upper bound is always needed. This upper bound is usually set up based on the knowledge on possible magnitude of the treatment difference and some practical considerations such as those mentioned earlier.

Efficiency

The apparent advantage associated with a sample size adaptive design is the flexibility in changing maximum information. As a trade off, the design may lose some efficiency as compared to a fixed sample size design. The amount of loss of efficiency depends on several factors, such as the policy for changing sample size, the closeness

of the initial sample size to the true sample size needed, and others. To determine which sample size strategy to use, the fixed or adaptive, it is advisable to compare the candidate strategies in terms of efficiency first through, say, computer simulation. The decision then can be made based on the result of comparison and the assessment of the worth of the extra flexibility at the price of some efficiency.

Operational Issue

Because sample size re-estimation based on observed treatment difference requires unblinding patient treatment assignment codes, it subjects to the usual concerns for unblinded interim analysis and proper operational measures need to be taken to prevent possible occurrence of operational biases. In general, the trial sponsor should not have access to the information revealed in the analysis for sample size re-estimation. The sample size re-estimation is ideally performed by an independent party, e.g., an independent data safety monitoring board, rather than the sponsor. After the analysis for sample size re-estimation, only the new sample size is conveyed to the sponsor without disclosing the details of the interim analysis outcomes.

In general, the study protocol needs to include justification for performing sample size re-estimation using unblinded data. There are, however, clinical trials for which interim unblinding data is necessary due to reasons other than re-estimating sample size. For example, in most of cancer trials, complete blinding treatment assignments is almost impossible because of, for instance, the different drug delivery methods associated with the testing treatment and control treatment. For long-term mortality trials, because of ethic concerns, it is necessary to monitor the safety and efficacy of study drugs in an unblinded fashion. Because for such trials unblinding treatment codes is inevitable, it is natural for one to use the unblinded treatment information to adjust the total sample size if needed.

For a trial with sample size re-estimation based on unblinded data, in order to maintain the integrity of the trial, a high standard for trial conduct must be maintained. If the trial is confirmatory, the timing, the method for the sample size re-estimation, the method for later data analysis, and the standard operational procedure related to the sample size re-estimation need to be provided in the protocol and complied with.

STATISTICAL TEST BASED ON MODIFIED SAMPLE SIZE

Over the years, statistical methods have been developed for sample size re-estimation based on interim estimate of the variation of the response variable (see, e.g., Refs. [7–11]). Recently, several methods have been developed to allow sample size re-estimation based on interim treatment difference. The main objective of these new methods is

to utilize the updated knowledge on the treatment effect during a clinical trial to calibrate the total sample size to achieve the desired level of statistical power and to maintain the Type I error rate at the target level. The proposed procedures can be categorized into several groups by the way of approaching the problem.

Conditional Type I Error Function

Proschan and Hunsberger^[2] proposed a two-stage trial design. With this approach, the treatment difference is observed and tested at the end of the first stage of the trial. If the null hypothesis is not rejected at the time, the trial is extended to the second stage with more patients recruited and the hypothesis is then tested at the end of the second stage. The number of the patients needed for the second stage of the trial is calculated based on the conditional power approach using the observed treatment difference at the first stage of the trial. A key to their approach is the conditional Type I error function that regulates the critical value used for the second-stage testing and the Type I error rate associated with the procedure.

Liu and Chi^[12] later modified Proschan and Hunsberger's procedure by introducing a more general, conditional Type I error function. The total sample size, the critical values for rejection and acceptance of the null hypothesis for the first stage and the second stage of the trial can be chosen so that a set of design constraints including those on Type I and Type II error rates for the individual stages and for the overall are satisfied.

Combining Normal Scores Through Weighting

Cui et al.,^[3] as mentioned before, proposed a flexible statistical test allowing sample size adaptation for group sequential designs. This adaptive test procedure is also readily for use in the multistage design setting.^[13] With this procedure, the test statistic after the sample size modification is a weighted summation of the original normal score statistics for the data collected before and after the sample size modification, respectively. This test procedure increases the statistical power when the sample size increases and always maintains the Type I error rate at the target level regardless of how the new sample size is projected. This adaptive strategy is easy to use and readily applicable to many common large-sample tests, e.g., logrank test for survival analysis, which approximately follows a Brownian motion process.^[3] Other methods of combining normal scores for the grouped data are also available in the literature. For instance, Shen and Fisher^[14] proposed a different weighting scheme based on the concepts of variance-spending and self-designing clinical trial.^[15] The total sample size and weights are adjusted as the trial progresses based on the data available at the time of adjustment. Their test statistic is asymptotically normal when the random weights depend only on the sample path

of the test statistic and satisfy the condition that the sum of the squared weights at the time of the termination of the trial is unity. This leads to easy calculation of p value and a controlled Type I error rate but no interim testing is allowed by the procedure.

Combining p Values

Based on Fisher's combination test, Bauer and Köhne^[16] proposed a two-stage procedure. Let p_1 and p_2 be the p values of the test based on the subsamples at the first stage and the second stage of the trial, and let α_1 and α be the significance levels for the first stage and for the overall, respectively. With their approach, after extending the trial to the second stage, following the first stage at which the null hypothesis is not rejected, the null hypothesis is tested again by comparing the product $p_1 p_2$ with $\exp[-0.5\chi^2_{4,1-\alpha}]$, where $\chi^2_{4,1-\alpha}$ is the $(1-\alpha)$ -quantile of the χ^2 distribution with 4 degrees of freedom. With a proper choice of α_1 , a desired overall total Type I error rate can be maintained. Bauer and Köhne's method was modified by several investigators. For example, Lehman and Wassmer^[17] proposed to use an inversed normal score to combine p values from different stages of the trial.

Penalizing p Value

For the methods mentioned above, criteria can be implemented to allow termination of the trial early for futility. Early termination of a trial for futility has been used to avoid further wasting of resources as well as to reduce Type I error rate to maintain it at a desired level.^[4,18]

When a sample size adaptation strategy is used, the control of Type I error rate is achieved, e.g., by either modifying the critical value or imposing a p value penalty (see, e.g., Ref. [2]), or by modifying the test statistics (see, e.g., Refs. [3,14]). In the latter case, the test may be more flexible but less efficient than a fixed sample size approach when the initially projected sample size is accurate.

CONCLUSION

One major challenge nowadays to clinical trials stems from uncertainties about important trial design parameters, e.g., the true treatment difference, as a result of rapid advancement in discovery of new drugs or new indications for existing drugs. A flexible design allowing sample size modification based on the observed interim treatment difference appears to be a reasonable solution to this problem. With a sample size adaptation approach, a portion of the trial is used as an internal pilot part^[1] of the trial, and its outcome is used to reassure or modify initially projected total sample size.

Sample size adjustment based on the observed treatment difference is a part of the broader context in adaptation of clinical trial design. The way to use such a strategy starts with a careful sample size plan based on the best available information about the treatment difference and variation of the response variable and all other important trial considerations. A sample size adaptation design, on the top of a carefully planned initial sample size, provides an ability for further fine tuning of the total sample size based on updated treatment information and an extra assurance on the total sample needed. These two benefits are particularly important for large-scale clinical trials, involving significant complexity and investment. At present, research in sample size re-estimation is continually active, focusing on new methodologies, new applications, and the properties of the existing methods.^[19–23]

Sample Size Re-estimation Design with Robust Power

Lu Cui

Data and Statistical Science, AbbVie Inc., North Chicago, Illinois, U.S.A.

Abstract

Flexible sample size design has been used as an alternative to fixed sample size design to achieve robust power and better efficiency of a clinical study. In this entry, the objective and performance evaluation of flexible sample size designs are discussed. Group sequential design and sample size re-estimation design—two kinds of popular flexible sample size designs—are introduced and compared. The implementation of flexible sample size design with design optimization is illustrated with examples.

Keywords: Sample size; Power; Group sequential design; Sample size re-estimation.

INTRODUCTION

Flexible sample size design has been used in clinical trials as an alternative to traditional fixed sample size design to achieve robust power and trial efficiency. Two kinds of flexible sample size designs often used are group sequential (GS) design and sample size re-estimation (RE) design. Both designs allow adjustment of the final sample size of a trial, N^* , based on unblinded interim treatment information. The key difference is that the former has fixed maximum sample size with a few interim time points for potential early stopping, but the latter allows varying final stopping time or final sample size after interim analysis.

This entry focuses on concepts and issues related to flexible sample size design. With the introduced objective of flexible sample size design and the corresponding performance evaluation criteria, GS and RE designs are compared. Implementation with design optimization is illustrated with examples.

LITERATURE REVIEW

The idea of statistical inference based on trial with flexible sample size can be traced back to Stein's two-stage procedure proposed in the 1940s.^[1] The interest surged due to increasing challenges in modern clinical trials in the early 1990s. To use interim data to improve clinical trial quality, Wittes and Brittain proposed the idea of internal piloting in clinical studies.^[2] The concept triggered waves of research in adaptive clinical trial designs, including flexible sample size design based on unblinded interim data. A method to handle the obtained stage-wise data via combining p values was given by Bauer and Köhne.^[3] Proschan and Hunsberger proposed a two-stage sample size RE design^[4] based on unblinded interim treatment difference with recalculated

final critical value to control type I error rate. Cui, Hung, and Wang^[5,6] and Lehman and Wassmer^[7] proposed methods to combine unblinded sample size RE with GS design via a re-weighting scheme. Different opinions advocating the use of GS approach rather than sample size RE design were given by Tsiatis and Mehta^[8] and Jennison and Turnbull^[9,10] based on point-wise efficiency consideration. Liu, Zhu, and Cui^[11] studied the design problem from different perspectives aiming at a robust design performance. Unlike Tsiatis and Mehta's work looking for a point-wise optimal flexible sample size design, Liu, Zhu, and Cui focused on optimal flexible sample size design with robust power for a range of the underlying parameter of interest. Wu and Cui showed^[12] that an RE design optimally chosen under the definition of Liu, Zhu, and Cui generally outperformed GS design. In fact, the optimal RE design can be obtained through global search of the best combination of the timing of the interim analysis, sample size of interim analysis, and weight used in the combination test.^[13] Among other works, an approach based on the concept of promising zone (PZ) became popular.^[14,15] A more general adaptive design method was proposed by Müller and Schäfer.^[16] By re-calculating critical values to control conditional type I error rate, the method allows modification of sample size as well as other trial parameters. Gao, Ware, and Mehta^[17] established the equivalence relationship among the methods by Proschan and Hunsberger; Cui, Hung, and Wang; and Müller and Schäfer. Because of its potential to improve quality of industry-sponsored clinical trials, flexible sample size design is of significant interest of drug developers and regulatory agencies. General regulatory guidances were issued by the U.S. Food and Drug Administration^[18] and the European Medicine Agency^[19] on adaptive clinical trials including flexible sample size design.

This short entry is to introduce flexible sample size design via sample size RE design and to discuss the related

issues. For this purpose, the design proposed by Cui, Hung, and Wang^[5,6] is particularly chosen to represent RE design because of its computational simplicity and maximum flexibility. Comparison of RE design with the GS design is provided to illustrate ideals. More references related to flexible sample size design can be found in literatures.^[20–29]

OBJECTIVE OF FLEXIBLE SAMPLE SIZE DESIGN

First consider a case of fixed sample size design under two-arm clinical trial setting. Assume that the outcomes of the primary efficacy measurement, X for placebo and Y for the new treatment, follow normal distributions with mean μ_0 and μ_1 , respectively, and with a common variance $0.5\sigma^2$. The experiment is to demonstrate that the new treatment is better than placebo based on testing the one-sided hypothesis,

$$H_0 : \delta = 0 \text{ vs. } H_1 : \delta > 0 \quad (1)$$

where $\delta = \mu_1 - \mu_0$ is the treatment difference. For fixed sample size design, the number of subjects per group needed to detect the treatment difference δ with power $1 - \beta$ at the significance level α is calculated as:

$$N = N(\delta) = \frac{(z_\alpha + Z_\beta)^2 \sigma^2}{\delta^2} \quad (2)$$

In the above, z_α is the upper α -quantile of the standard normal distribution. For simplicity, we further assume that $\sigma = 1$ is known. In the practice, σ is often readily estimated based on historical data or blinded interim data.

Since δ is unknown, to calculate the sample size, δ in Eq. 2 is replaced by a targeted treatment difference δ_0 . Determination of δ_0 can be a difficult task since it should be in line with the unknown true treatment difference δ essentially. Otherwise the projected sample size N based on δ_0 will be off the target leading to an either underpowered or overpowered study.

Flexible sample size design is to address the aforementioned difficulty. Unlike fixed sample size design, without an upfront accurate projection of the true treatment difference δ , flexible sample size design is to target the unknown treatment difference in a likely range, say, $[\delta_L, \delta_U]$. While fixed sample size design shoots a statistical power of $1 - \beta$ at a point value of δ_0 , the objective of flexible sample size design is to ensure a desirable study power of $1 - \beta$ for all true $\delta \in [\delta_L, \delta_U]$ through interim sample size assessment.

GROUP SEQUENTIAL AND SAMPLE SIZE RE-ESTIMATION DESIGNS

GS and RE approaches to flexible sample size design are briefly described below. Suppose that hypothesis (Eq. 1) is

to be repeatedly tested in a total of $K - 1$ interim analyses and in the final analysis. With a given α -spending function and the corresponding critical value C_k , $k = 1, \dots, K$, the test statistic of the usual (likelihood ratio) GS test in the k^{th} analysis is:

$$S_k = \frac{1}{\sqrt{n_k}} \sum_{i=1}^{n_k} (Y_i - X_i), \quad k = 1, \dots, K \quad (3)$$

where n_k is the sample size per group in the k^{th} interim analysis and $n_K = N$. The null hypothesis H_0 is rejected if $S_k > C_k$, and otherwise the trial proceeds to the next analysis and the sample size is incrementally increased. At the final analysis, H_0 is rejected if $S_K > C_K$ or the trial is inconclusive. Since the trial can be terminated early, the actual or the final sample size of the trial N^* can be smaller than the planned sample size or $N^* \leq N$.

For illustration, consider the RE design proposed by Cui, Hung, and Wang^[5,6] which is built on a K -analysis GS design with test statistics S_k and maximum sample size N . The hypothesis (Eq. 1) is then tested with test statistics $U_k = S_k$ as before for $k \leq l$. Assume that in the l^{th} interim analysis, the null hypothesis is not rejected, and subsequently the final sample size is re-estimated as $N^* = M$ per group. Let $b = (M - n_l) / (N - n_l)$, where $b < 1$ if $M < N$, $b > 1$ if $M > N$, or $b = 1$ if $M = N$. The remaining interim analyses after the l^{th} interim analysis can be performed with, say, m_{l+j} subjects per group, where $m_{l+j} = b(n_{l+j} - n_l) + n_l$, $j = 1, \dots, K - l$ and $m_K = M$. However, to control type I error rate, test statistic U_k is modified as:

$$U_k = S_l \sqrt{\frac{n_l}{n_k}} + \frac{\sum_{i=n_l+1}^{m_k} (Y_i - X_i)}{\sqrt{m_k - n_l}} \sqrt{\frac{n_k - n_l}{n_k}} \quad (4)$$

$k = l + 1, \dots, l + j, \dots, K$, and the hypothesis (Eq. 1) is further tested using U_k against C_k , $k = l + 1, \dots, l + j, \dots, K$. In general, the final sample size $N^* = M$ can be obtained via simulations using conditional power approach based on the interim data.

Test statistic U , proposed by Cui, Hung, and Wang, has been termed as CHW test or weighted RE method. Like GS method, it has controlled type I error rate. If the initial sample size remains unchanged, or $N^* = N$, the test statistic U_k reduces to the GS test S_k . This means that all GS tests form a subset of RE tests. The importance of this fact is that RE design in theory dominates GS design in term of achieving optimality.^[10]

Zhang, Cui, and Yang^[13] pointed out that the weight in Eq. 4 can be set as arbitrary fixed numbers satisfying $0 < w_1 < \dots < w_{K-1} < w_K = 1$. The test statistic U in Eq. 4, after the interim sample assessment, then becomes:

$$U_k = S_l \sqrt{\frac{w_l}{w_k}} + \frac{\sum_{i=n_l+1}^{m_k} (Y_i - X_i)}{\sqrt{w_k - w_l}} \sqrt{\frac{w_k - w_l}{w_k}} \quad (5)$$

$k=1+1,\dots,1+j,\dots,K$. The statistical testing at interim analysis can be conducted based on U_k as before with a given α -spending function evaluated at w_k as if w_k was information fraction. In the analysis, properly chosen n_k ($k \leq 1$) or m_k ($1 < k \leq K$) subjects per group are to be involved.

MEASURE OF ADAPTIVE PERFORMANCE

Recall the sample size calculation for the fixed sample size design. If the true δ is known, the sample size of the trial $N = N(\delta)$ is calculated at δ according to Eq. 2. The sample size $N(\delta)$ can be viewed as an ideal or a gold standard sample size since it is the perfect sample size that one may get to meet the power and type I error rate specifications. The notation $N(\delta)$ will particularly denote this gold standard sample size as a function of δ .

The above method motivates the performance measure of flexible sample size design based on the deviation of its final trial sample size N^* from the gold standard sample size $N(\delta)$. Such a deviation at each δ can be measured via sample size ratio (SR)^[11] or sample size difference (SD)^[12] defined as the following:

$$SR = \frac{N^*}{N(\delta)} - 1 \quad (6)$$

and

$$SD = N^* - N(\delta) \quad (7)$$

The average performance score (APS) then can be defined as the average of SR (APS_r) or SD (APS_d) over the range of δ :

$$APS_r = \int_{\delta_L}^{\delta_U} \left| \frac{E_{\delta}(N^*)}{N_{\delta}} - 1 \right| f(\delta) d\delta \quad (8)$$

$$APS_d = \int_{\delta_L}^{\delta_U} |E_{\delta}(N^*) - N_{\delta}| f(\delta) d\delta \quad (9)$$

In the above equations, $f(\delta) > 0$ is a tuning function. It can be chosen as a constant over $[\delta_L, \delta_U]$, if there is no detailed information about δ . Otherwise, $f(\delta)$, for example, can be chosen as a truncated normal density if one believes that likely values of δ are centered around a particular point in the interval.

The definition of APS allows to summarize the adaptive performance of a flexible sample size design over a range of δ by a single numerical value. Since APS penalizes both oversizing and undersizing the trial, a small value of APS generally means a smaller deviation from the true sample size required and consequently a smaller deviation from

the targeted power. Therefore, minimizing APS is desirable. This leads to the following definition of optimal flexible sample size design by Liu, Zhu, and Cui.^[11]

Definition

An optimal flexible sample size design is one for which the associated APS is minimized as compared to all flexible sample size designs.

This definition generally leads to a flexible sample size design with a close-to-target final sample size, and thus a robust power over $[\delta_L, \delta_U]$, achieving the objective of flexible sample size design. Since practically only a finite number of different sample size designs are considered at the design stage, the best flexible sample size design with the minimum APS value can always be found by comparing calculated APS values of the candidate designs.

PERFORMANCE COMPARISON AND DESIGN OPTIMIZATION

The APS provides an easy way to compare flexible sample size designs, including GS, RE, and PZ designs. The following examples show how to implement flexible sample size design with design optimization.

Example 1

Since fixed sample design can be viewed as a special case of flexible sample size design, the definition of APS optimality applies to fixed sample case. It can be shown that the optimal fixed size design among all fixed sample designs is the one with the sample size N calculated to target at the center of the interval $[\delta_L, \delta_U]$ or $\delta_0 = (\delta_L + \delta_U)/2$. In other words, when only knowledge available at the trial design stage is the range of δ , the best or a balanced fixed sample size strategy is to target at the midpoint of the range, which agrees with intuition.^[12]

Example 2

Liu, Zhu, and Cui^[11] considered the hypothesis testing problem (Eq. 1) and a set of candidate flexible sample size designs. The set consisted of four-look GS designs with O'Brien-Flemming (GSO) or Pocock (GSP) α -spending functions and with initial sample size $N = 40, 80, \dots, 1,000$ and four-look RE designs with the same spending functions (REO and REP designs) and initial sample sizes. There were 100 candidate flexible designs (25 of each type). In the example, the interim analyses were equally spaced. For GS design, an initial sample size was also the maximum sample size. For RE design, sample size increase was allowed after the sample size re-estimation in the second interim analysis with 50% of the initial sample size but the maximum sample size was capped at 1,000

subjects per treatment group for the sake of a fair comparison. The true treatment difference δ was assumed in the range $[\delta_L, \delta_U] = [0.1, 0.5]$. The objective was to find the best design among the candidate designs with a robust power over the range.

The performance score APS_r was calculated based on simulated data for all designs. The values of APS_r for the best GSO, GSP, as well as REO and REP designs were obtained as 75.4, 55.5, 50.3, and 37.2, respectively. The corresponding initial sample sizes were 160, 280, 160, and 240, respectively. Therefore, by Liu's Definition, the best GS design was the GS design with Pocock α -spending function and the maximum sample size $N = 280/\text{group}$ ($APS_r = 55.5$) which outperformed the best GS design with O'Brien-Fleming α -spending function and $N = 160/\text{group}$ ($APS_r = 75.4$). Even with the conservative O'Brien-Fleming α -spending function, the RE design with the initial sample size $N = 160$ ($APS_r = 50.3$) outperformed the best GS design ($APS_r = 55.5$). The winner among all candidate designs was the RE design with Pocock α -spending function and the initial sample size $N = 240$. This design had the smallest APS_r value of 37.2. Additional simulations showed that this design maintained the targeted statistical power about 90% or higher for $\delta \in [0.14, 0.5]$ or no less than 80% of power for the entire range $[0.1, 0.5]$. The design apparently achieved its objective with robust power and efficient average sample size for nearly all $\delta \in [\delta_L, \delta_U] = [0.1, 0.5]$.

Example 3

Zhang, Cui, and Yang^[13] studied the general CHW RE design with freely chosen weight w . Under a similar setting of example 2 with a four-look RE design and Pocock α -spending function, fixing $1 = 2$, the optimal RE design based on APS criterion was identified with $n_1 = 80$ and $w = (0.05, 0.1, 0.35, 1.0)$. The design was obtained through global search based on APS among possible choices of n_1 and w . The simulations in this study showed that even for the GS design, the APS optimization could help to find out robust GS design. Simulations also showed that RE design in general outperformed GS and PZ designs, while the latter two appeared to have comparable performance.

CONCLUSION

The main objective of flexible sample size design is to achieve a robust high statistical power of a clinical study. Based on the two commonly used flexible sample size designs, namely, GS and RE designs, the design performance evaluation and design optimization are illustrated. The examples show that an optimally chosen flexible design can achieve a robust statistical power over a wide range of likely values of the targeted parameter.

Sample Size: Negative Binomial With Unequal Follow-Up Times

Yongqiang Tang

Shire, Lexington, Massachusetts, U.S.A.

Abstract

Recurrent events are common in clinical trials. Examples include exacerbations in chronic obstructive pulmonary disease, relapses in multiple sclerosis, seizures in epileptics, and hospitalizations. In late-phase confirmatory trials, the primary endpoint is generally the total number of events experienced by the subjects. The recurrent event counts often exhibit overdispersion, in the sense, that the variance exceeds the mean. Negative binomial (NB) regression has become widely used to analyze recurrent event data in clinical trials since it provides a natural way to account for overdispersion. Several previously developed methods for calculating sample size for the NB regression assume equal follow-up time for all subjects by ignoring early dropouts or by setting the follow-up time for all individuals to be the mean follow-up time. Ignoring variability in the duration of the follow-up generally leads to underpowered studies. In this entry, we review the sample size calculation methods for comparing two NB rates in superiority, non-inferiority, and equivalence trials with unequal follow-up times.

Keywords: Equivalence trial; Fixed margin approach; Negative binomial distribution; Non-inferiority margin; Non-inferiority trial; Overdispersion; Power and sample size; Superiority trial.

INTRODUCTION

Recurrent events are common in clinical trials. Examples include exacerbations in chronic obstructive pulmonary disease, relapses in multiple sclerosis, seizures in epileptics, and hospitalizations. In late-phase confirmatory trials, the primary endpoint is generally the total number of events experienced by the subjects. The recurrent event counts often exhibit overdispersion, in the sense, that the variance exceeds the mean.

Negative binomial (NB) regression has become widely used to analyze recurrent event data in clinical trials since it provides a natural way to account for overdispersion. Several previously developed methods for calculating sample size for the NB regression assume equal follow-up time for all subjects by ignoring early dropouts or by setting the follow-up time for all individuals to be the mean follow-up time. Ignoring variability in the duration of the follow-up generally leads to underpowered studies. In this entry, we review the sample size calculation methods for comparing two NB rates in superiority, non-inferiority (NI), and equivalence trials with unequal follow-up times.

NB DISTRIBUTION

The NB distribution [denoted by $Y \sim \text{NB}(\mu, \kappa)$] is the probability distribution of the number of failures Y before

$k = 1/\kappa$ successes in a series of independent Bernoulli trials with the same probability $p = 1/(1 + \kappa \mu)$ of success.

$$\Pr(Y = y) = \frac{\Gamma(y + 1/\kappa)}{y! \Gamma(1/\kappa)} p^{1/\kappa} (1 - p)^y \quad (1)$$

where μ is the mean and κ is the dispersion parameter. For count data, the NB distribution is often interpreted as a gamma mixture of Poisson distribution. That is, if Y follows a Poisson distribution with mean $\varepsilon\mu$ and ε is gamma distributed with mean 1 and variance κ , the marginal distribution of Y is $\text{NB}(\mu, \kappa)$. This representation does not require $k = 1/\kappa$ to be an integer. The random effect ε captures the between-subject heterogeneity in event rates, and κ measures the degree of heterogeneity. Including important risk factors in the model may reduce heterogeneity. The NB distribution tends to fit the overdispersed count data better than the Poisson distribution,^[1,2] and its mean is always less than its variance.^[3]

$$\begin{aligned} E(Y) &= E[E(Y | \varepsilon)] = \mu, \\ \text{var}(Y) &= E[\text{var}(Y | \varepsilon)] + \text{var}[E(Y | \varepsilon)] = \mu + \kappa\mu^2 \end{aligned} \quad (2)$$

The NB distribution belongs to the family of mixed Poisson distributions. The gamma distribution is commonly used as the mixing distribution because the corresponding marginal distribution has a closed form, which is NB.^[3,4]

ANALYSIS OF COUNT DATA

Suppose in a clinical trial, n subjects are randomized to the experimental ($g = 1$) or control ($g = 0$) treatment. Let t_{gj} be the follow-up time and y_{gj} be the number of observed events for subject $j = 1, \dots, n_g$ in group g . We assume constant event rate over time, and $y_{gj} \sim \text{NB}(\mu_{gj}, \kappa)$, where $\lambda_g = \exp(\gamma_g)$ is the event rate for group g , and $\mu_{gj} = \lambda_g t_{gj}$. In SAS, the NB regression can be fitted using the code,

```
proc genmod data =xxx;
class trt;
model y= trt /offset=logt link=log dist=nb noLOGNB;
run;
```

The offset term $\log(t_{gj})$ accounts for different follow-up periods for different subjects. When the *noLogNB* option is employed, the dispersion parameter is estimated based on κ rather than $\log(\kappa)$. The real data may not exhibit overdispersion^[1] if nearly all subjects have no or only one event (e.g., due to mild disease condition or short follow-up time), and the estimation based on $\log(\kappa)$ may fail to converge because of the restriction $\kappa > 0$.

Throughout, we assume a lower event rate is desirable. The treatment effect is often measured by the rate ratio $\exp(\beta) = \lambda_1 / \lambda_0$ or equivalently by the relative rate reduction $\text{RRR} = 1 - \lambda_1 / \lambda_0 = 1 - \exp(\beta)$. Let parameters with $\hat{\cdot}$ denote the maximum likelihood estimate (MLE). By equations (2.7a), (2.7b), and (2.8) of Lawless,^[4] the Fisher information matrix for $(\gamma_0, \gamma_1, \kappa)$ is diagonal $\text{diag}(e_0, e_1, e_*)$, where $e_g = \sum_{j=1}^{n_g} \lambda_g t_{gj} / (1 + \kappa \lambda_g t_{gj})$ and e_* is irrelevant in the sample size calculation. Therefore, $\hat{\gamma}_0, \hat{\gamma}_1$, and $\hat{\kappa}$ are asymptotically independent, $\text{var}(\hat{\lambda}_g) = e_g^{-1}$, and the variance of $\hat{\beta} = \hat{\gamma}_1 - \hat{\gamma}_0$ is:

$$\text{var}(\hat{\beta}) = \text{var}(\hat{\gamma}_0) + \text{var}(\hat{\gamma}_1) = e_0^{-1} + e_1^{-1} \quad (3)$$

The variance of $\hat{\beta}$ can also be obtained from the observed information matrix. The two variance estimates are asymptotically equivalent. The two-sided 100(1 - α)% confidence interval (CI) for β is:

$$[c_l, c_u] = \left[\hat{\beta} - Z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})}, \hat{\beta} + Z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} \right] \quad (4)$$

where $\widehat{\text{var}}(\hat{\beta})$ is the variance of $\hat{\beta}$ evaluated at the MLE, and z_p is the p^{th} percentile of the standard normal distribution. The CI for $\exp(\beta) = \lambda_1 / \lambda_0$ is $[\exp(c_l), \exp(c_u)]$.

In a superiority trial, the control treatment is placebo or an active treatment, and the objective is to demonstrate that the experimental treatment can lower the event rate. The hypothesis can be expressed as:

$$H_0 : \lambda_0 = \lambda_1 \text{ or } \beta = 0 \text{ vs } H_1 : \lambda_0 \neq \lambda_1 \text{ or } \beta \neq 0 \quad (5)$$

if $c_u < 0$ or equivalently $\exp(c_u) < 1$, one can claim that the experimental treatment can significantly reduce the event rate compared to the control treatment.

In a NI trial, the control is an active treatment whose effect is well defined, and the objective is to show that the experimental treatment is not worse than the active control by M_0 , where $M_0 > 1$ is a prespecified NI margin. The NI trials could be analyzed using a fixed margin approach or the synthesis method.^[5] We focus on the fixed margin approach since it is recommended by the regulatory guidelines.^[5,6] The margin M_0 is generally chosen to be close to 1 in order to demonstrate that the new treatment is not materially inferior to the active comparator (refer to the Guidelines by United States Food and Drug Administration and the European Medicines Agency's Committee for Medicinal Products for Human Use^[5,6] for more details on the specification and interpretation of the NI margin). In NI trials, the hypothesis can be written as:

$$H_0 : \frac{\lambda_1}{\lambda_0} \geq M_0 \text{ versus } H_1 : \frac{\lambda_1}{\lambda_0} < M_0 \quad (6)$$

or equivalently as:

$$H_0 : \beta \geq \log(M_0) \text{ versus } H_1 : \beta < \log(M_0) \quad (7)$$

If the upper limit of the CI for $\exp(\beta) = \lambda_1 / \lambda_0$ satisfies $\exp(c_u) < M_0$, one can claim that the experimental treatment is not significantly inferior to the active comparator.

In an equivalence trial, the objective is to demonstrate that the two treatments are clinically equivalent. If the CI for $\exp(\beta)$ lies completely within the interval $[M_l, M_u]$, we can claim clinical equivalence of the two treatments, where $M_l < 1$ and $M_u > 1$ are two prespecified margins. The hypothesis can be written as:

$$H_0 : \frac{\lambda_1}{\lambda_0} \geq M_u \text{ or } \frac{\lambda_1}{\lambda_0} \leq M_l \text{ versus } H_1 : M_l < \frac{\lambda_1}{\lambda_0} < M_u \quad (8)$$

or equivalently as:

$$H_0 : \beta \geq \log(M_u) \text{ or } \beta \leq \log(M_l) \text{ versus } H_1 : \log(M_l) < \beta < \log(M_u) \quad (9)$$

One may refer to Chow, Wang, and Shao^[7] for more detailed discussions on superiority, NI, and equivalence trials, where they also provide methods for sample size determination for different types of endpoints.

SAMPLE SIZE FOR SUPERIORITY TRIALS

In a superiority trial, the event rates are statistically different between the two treatment groups if the CI of $\hat{\beta}$ excludes 0. Both $Z = (\hat{\beta} - \beta) / \sqrt{\widehat{\text{var}}(\hat{\beta})}$ and $-Z$ asymptotically follow the standard normal distribution $N(0, 1)$. Then:

$$\begin{aligned} \Pr(c_u < 0) &= \Pr(\hat{\beta} + z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} < 0) \\ &= \Pr\left(Z < \frac{-z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} - \beta}{\sqrt{\widehat{\text{var}}(\hat{\beta})}}\right) \end{aligned}$$

$$\begin{aligned} &\approx \Pr\left(Z < -z_{1-\alpha/2} - \frac{\beta}{\sqrt{\text{var}(\beta)}}\right) \\ &\approx \Phi\left(\frac{-\sqrt{n}\beta}{\sqrt{(d_0p_0)^{-1} + (d_1p_1)^{-1}}} - z_{1-\alpha/2}\right) \end{aligned} \quad (10)$$

where p_g is the proportion of subjects randomized to treatment group g and $d_g = E[\lambda_g t_{g|j} / (1 + \kappa \lambda_g t_{g|j})]$. The derivation of Eq. 10 relies on the large sample approximations $\widehat{\text{var}}(\hat{\beta}) / \text{var}(\beta) \approx 1$, and $e_g \approx n_g d_g$. Similarly, we have:

$$\Pr(c_1 > 0) \approx \Phi\left(\frac{\sqrt{n}\beta}{\sqrt{(d_0p_0)^{-1} + (d_1p_1)^{-1}}} - z_{1-\alpha/2}\right) \quad (11)$$

if $c_1 > 0$, one would conclude that the control treatment is better than the experimental treatment, and this is undesired. But the probability $\Pr(c_1 > 0)$ is negligible compared to $\Pr(c_u < 0)$ if the experimental treatment is truly effective in lowering the event rate (i.e., $\lambda_1 < \lambda_0$, and λ_1 is not too close to λ_0 to be of practical interest). The power is:

$$\begin{aligned} P &= \Pr(c_1 > 0) + \Pr(c_u < 0) \approx \Pr(c_u < 0) \\ &\approx \Phi\left(\frac{\sqrt{n}|\beta|}{\sqrt{(d_0p_0)^{-1} + (d_1p_1)^{-1}}} - z_{1-\alpha/2}\right) \end{aligned} \quad (12)$$

Inverting Eq. 12 yields the required total sample size.^[3]

$$n_{\text{tar}} = [(d_0p_0)^{-1} + (d_1p_1)^{-1}] \frac{(z_{1-\alpha/2} + z_p)^2}{\beta^2} \quad (13)$$

Under equal allocation ($p_0 = p_1 = 1/2$), the total size is:

$$n_{\text{tar}} = 2(d_0^{-1} + d_1^{-1}) \frac{(z_{1-\alpha/2} + z_p)^2}{\beta^2} \quad (14)$$

Eqs. 12–14 are also valid if $\lambda_1 > \lambda_0$ (i.e., $\beta > 0$), and the objective is to demonstrate that the experimental treatment can increase the event rate.

The power and sample size formulae reviewed in this entry are derived based on the Wald test from the NB regression, and they generally work well in moderate to large samples. Their performance deteriorates when the sample size becomes small. For example, Eq. 12 may slightly underestimate the power of the Wald test in small samples^[3] possibly because the dispersion parameter κ is underestimated^[8] in the MLE procedure (this is analogous to the analysis of variance). Partially for the same reason, the Wald-type test may not be able to control the type I error at the nominal level in small samples, and more robust tests shall be used to analyze small trials.

SAMPLE SIZE FOR NI TRIALS

In a NI trial, the experimental treatment is not materially worse than the active control if the whole CI of β is below $\log(M_0)$. The power is:^[9]

$$\begin{aligned} \Pr(c_u < \log(M_0)) &= \Pr(\hat{\beta} + z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} < \log(M_0)) \\ &= \Pr\left(Z < \frac{-z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} - \beta + \log(M_0)}{\sqrt{\text{var}(\beta)}}\right) \\ &\approx \Phi\left(\frac{\sqrt{n}\beta^*}{\sqrt{(d_0p_0)^{-1} + (d_1p_1)^{-1}}} - z_{1-\alpha/2}\right) \end{aligned} \quad (15)$$

where $\beta^* = \log(M_0 \lambda_0 / \lambda_1)$. The sample size is:^[9]

$$n_{\text{tar}} = [(d_0p_0)^{-1} + (d_1p_1)^{-1}] \frac{(z_{1-\alpha/2} + z_p)^2}{\beta^{*2}} \quad (16)$$

Eq. 16 looks similar to Eq. 13 except that $\beta^2 = \log^2(\lambda_0 / \lambda_1)$ is replaced by $\beta^{*2} = \log^2(M_0 \lambda_0 / \lambda_1)$. However, it would be cautious to calculate the sample size for a NI trial using the sample size calculation software for superiority trials because the event rates could be implicitly modified as $\lambda_1 = \lambda_0 \exp(\beta^*)$ if the software requires only the values for λ_0 and $\exp(\beta^*)$.^[9]

SAMPLE SIZE FOR EQUIVALENCE TRIALS

In an equivalence trial, the two treatments are not clinically different if the whole CI of β falls completely within the interval $[\log(M_1), \log(M_u)]$. The power is:

$$\begin{aligned} P &= \Pr(c_u = \hat{\beta} + z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} < \log(M_u) \text{ and } \\ &\quad \hat{\beta} - z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} > \log(M_1)) \\ &= \Pr\left(\frac{z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} - \beta + \log(M_1)}{\sqrt{\text{var}(\beta)}} < Z \right. \\ &\quad \left. < \frac{-z_{1-\alpha/2} \sqrt{\widehat{\text{var}}(\hat{\beta})} - \beta + \log(M_u)}{\sqrt{\text{var}(\beta)}}\right) \\ &\approx \Phi\left(\frac{\sqrt{n} \log(M_u \lambda_0 / \lambda_1)}{\sqrt{(d_0p_0)^{-1} + (d_1p_1)^{-1}}} - z_{1-\alpha/2}\right) \\ &\quad + \Phi\left(\frac{-\sqrt{n} \log(M_1 \lambda_0 / \lambda_1)}{\sqrt{(d_0p_0)^{-1} + (d_1p_1)^{-1}}} - z_{1-\alpha/2}\right) - 1 \end{aligned} \quad (17)$$

In the special case when $\lambda_0 = \lambda_1$ and $-\log(M_1) = \log(M_u)$ (i.e., $M_u M_1 = 1$), the sample size is given by:^[9]

$$n_{\text{tar}} = [(d_0p_0)^{-1} + (d_1p_1)^{-1}] \frac{(z_{1-\alpha/2} + z_{(1+p)/2})^2}{\log^2(M_u)} \quad (18)$$

In general, a closed-form sample size formula does not exist although some approximations can be derived when $\beta = \log(\lambda_1 / \lambda_0)$ is sufficiently close to 0^[7,9] or far from 0.^[9,10] We would recommend using a numerical method (e.g., bisection method) to find the sample size at which the power in Eq. 17 is not less than the target power.

SAMPLE SIZE BOUNDS

By using Jensen's inequality and Cauchy-Schwarz inequality, Tang^[3] derived the lower (d_{gl}) and upper (d_{gu}) bounds on d_g :

$$d_{gl} = \frac{\lambda_g v_g^2}{v_g + \kappa \lambda_g E(t_{gj}^2)} \leq d_g \leq d_{gu} = \frac{\lambda_g v_g}{1 + \kappa \lambda_g v_g} \quad (19)$$

where $v_g = E(t_{gj})$ is the mean follow-up time in group g . Replacing d_g by d_{gu} in the power and sample size formulae leads to a lower sample size bound and an upper power bound and replacing d_g by d_{gl} leads to an upper sample size bound and a lower power bound.

The lower size bound is the required size when all subjects in treatment group g are followed for the same time $t_{gj} = v_{tg}$ and can be decomposed into two terms:

$$n_l = \left[\frac{1}{p_0 \lambda_0 v_{t_0}} + \frac{1}{p_1 \lambda_1 v_{t_1}} \right] f + (p_0^{-1} + p_1^{-1}) \kappa f \quad (20)$$

where $f = (z_{1-\alpha/2} + z_p)^2 / \beta^2$ in a superiority trial, and $f = (z_{1-\alpha/2} + z_p)^2 / \beta^2$ in a NI trial. In an equivalence trial, the sample size bounds can be obtained by inverting the power bounds numerically, and $f = (z_{1-\alpha/2} + z_{(1+p)/2})^2 / \log^2(M_u)$ in the special case when $\lambda_0 = \lambda_1$ and $-\log(M_l) = (M_u)$. In Eq. 20, the first term is the required size ignoring overdispersion (i.e., the count data follow Poisson distribution), and the second term corrects for overdispersion. In the upper size bound, another term is added to account for variation in the duration of the follow-up.

$$n_u = n_l + \kappa f \left[\frac{1}{p_0} CV_0^2 + \frac{1}{p_1} CV_1^2 \right] \quad (21)$$

where $CV_g = \sqrt{\text{var}(t_{gj})} / v_{tg}$ is the coefficient of variation for t_{gj} . Note that n_u can be further bounded by:

$$n_u \leq \tilde{n}_u = n_l + \kappa f \left[\frac{t_{m_0} - v_{t_0}}{v_{t_0}} + \frac{t_{m_1} - v_{t_1}}{v_{t_1}} \right] \quad (22)$$

where t_{m_g} is the maximum follow-up time in group g .

Tang^[3] suggested using n_u as a conservative sample size estimate for several reasons: 1) it only slightly overestimates the required size in the NB regression especially for design 1 considered in the next section; 2) it is the required size for the robust Wald test from the Andersen-Gill^[11] model, and thus robust against the misspecification of the mixing distribution in the mixed Poisson regression; and 3) it requires information only on the mean and variance of t_{gj} , which are easier to compute than d_g .

The dispersion parameter κ is generally not reported in the medical literature. The inequalities given in the section can be used to back-calculate κ based on the reported point estimates of the event rate and rate ratio and their CI (refer to Tang^[9] for a numerical illustration).

ESTIMATION OF d_g , $E(t_{gj})$, AND $E(t_{gj}^2)$

Analytic expressions for d_g , $E(t_{gj})$, and $E(t_{gj}^2)$ are given for two types of designs studied by Tang.^[9] Note that $v_{tg} = E(t_{gj})$ and $E(t_{gj}^2)$ are needed in calculating the lower and upper size bounds, and d_g is required for computing n_{tar} . In general, evaluating d_g requires numerical integration and can be done using the SAS QUAD subroutine.^[3]

In design 1, the planned treatment duration is τ_c years for all patients, and the loss to follow-up is assumed to be exponentially distributed with mean δ^{-1} years and independent of the event process. The overall dropout rate is $w_c = 1 - \exp(-\delta \tau_c)$ and:

$$\begin{aligned} d_g &= E \left[\frac{\lambda_g t_{gj}}{1 + \kappa \lambda_g t_{gj}} \right] = \frac{1}{\kappa} - E \left(\frac{1}{\kappa + \kappa^2 \lambda_g t_{gj}} \right) \\ &= \frac{1}{\kappa} - \frac{\exp(-\delta \tau_c)}{\kappa + \kappa^2 \lambda_g \tau_c} - \int_0^{\tau_c} \frac{\delta \exp(-\delta t)}{\kappa + \kappa^2 \lambda_g t} dt \end{aligned} \quad (23)$$

$$E(t_{gj}) = \frac{1 - \exp(-\delta \tau_c)}{\delta} = \frac{w_c}{\delta},$$

$$E(t_{gj}^2) = \frac{2[1 - (1 + \delta \tau_c) \exp(-\delta \tau_c)]}{\delta^2}$$

In design 2, we assume patients are enrolled during an accrual period of τ_a years, and after the closure of recruitment, subjects are followed for an additional τ_c years.^[12] That is, all subjects will be administratively censored at time $\tau_a + \tau_c$. The loss to follow-up distribution is the same as design 1. Suppose the patient entry time e_{gj} is distributed as $g(e_{gj}) = \eta \exp(-\eta e_{gj}) / (1 - \exp(-\eta \tau_a))$.^[13] The entry distribution is convex (faster patient entry at the beginning) if $\eta > 0$, concave (lagging patient entry) if $\eta < 0$, and uniform $g(e_{gj}) = 1/\tau_a$ if $\eta \rightarrow 0$. Then:

$$\begin{aligned} d_g &= \frac{1}{\kappa} - \int_0^{\tau_c} \frac{\delta \exp(-\delta t)}{\kappa + \kappa^2 \lambda_g t} dt - \int_0^{\tau_a} \frac{\exp(-\delta(t + \tau_c))}{\kappa + \kappa^2 \lambda_g(t + \tau_c)} h(t) dt \\ E(t_{gj}) &= \frac{1}{\delta} - \frac{\exp(-\delta \tau_c)}{\delta} h_1 \\ E(t_{gj}^2) &= \frac{2}{\delta^2} \left\{ 1 - \exp(-\delta \tau_c) \left[(\delta \tau_c + 1) h_1(t) + \delta h_2(t) \right] \right\} \end{aligned} \quad (24)$$

where,

$$\begin{aligned} h(t) &= \frac{\delta + (\eta - \delta) \exp(\eta(t - \tau_a))}{1 - \exp(-\eta \tau_a)} \\ h_1 &= \frac{\eta \exp(-\delta \tau_a) - \exp(-\eta \tau_a)}{\eta - \delta} \\ h_2 &= \frac{\eta \exp(-\eta \tau_a) [(\eta - \delta) \tau_a - 1] \exp((\eta - \delta) \tau_a) + 1}{1 - \exp(-\eta \tau_a) (\eta - \delta)^2} \end{aligned} \quad (25)$$

For uniform patient entry ($\eta \rightarrow 0$), Eq. 25 reduces to:

$$\begin{aligned} h(t) &= \delta \frac{\tau_a - t}{\tau_a} + \frac{1}{\tau_a} \\ h_1 &= \frac{1 - \exp(-\delta \tau_a)}{\delta \tau_a} \\ h_2 &= \frac{1 - (\delta \tau_a + 1) \exp(-\delta \tau_a)}{\delta^2 \tau_a} \end{aligned} \quad (26)$$

ALTERNATIVE APPROACHES

Sample Size Assuming Equal Follow-Up Times

The sample size formulae comparing two NB rates have been developed for superiority trials^[14–16] (method 2 of Zhu and Lakkis^[15]), NI trials^{[16][17]} (method 1 of Zhu^[17]), and equivalence trials^[17] under the assumption of equal follow-up. This could be achieved by ignoring information from early dropouts for design 1 or by setting the follow-up time for all individuals to be the mean follow-up time. If data from early dropouts are ignored, the sample size after adjusting for dropout rate is overestimated by about 8%–45% in the numerical examples given by Tang.^[3] If the length of the follow-up for all individuals is set to be the mean follow-up time, the resulting sample size is in fact identical to the lower size bound n_l . The sample size formula for superiority trials developed by Cook^[12] is also identical to the lower size bound n_l .^[3]

Sample Size Using Variance Under Null Hypothesis

Zhu and Lakkis^[15] (method 3 in their study) proposed one variation of the sample size formula for superiority trials. The approach uses the variance derived under $H_0: \lambda_0 = \lambda_1$ by setting $t_{gj} = v_t = v_0 = v_1$. Specifically,

$$n_{zl} = \frac{[z_{1-\alpha/2} \sqrt{V_0} + z_p \sqrt{V_1}]^2}{\beta^2} \quad (27)$$

where $\tilde{\lambda}_0 = \tilde{\lambda}_1 = p_0 \lambda_0 + p_1 \lambda_1$ is the expected value of the MLE under H_0 ,

$$\begin{aligned} V_1 &= (p_0^{-1} + p_1^{-1})\kappa + (p_0 \tilde{\lambda}_0 v_t)^{-1} + (p_1 \tilde{\lambda}_1 v_t)^{-1}, \\ V_0 &= (p_0^{-1} + p_1^{-1})\kappa + (p_0 \tilde{\lambda}_0 v_t)^{-1} + (p_1 \tilde{\lambda}_1 v_t)^{-1} \end{aligned} \quad (28)$$

The numerical examples in Zhu and Lakkis^[15] indicate that Eq. 27 generally produces similar sample size estimate to the lower size bound given in Eq. 20 because $V_0 \approx V_1$ and:

$$n_l = \frac{[z_{1-\alpha/2} + z_p]^2 V_1}{\beta^2} = \frac{[z_{1-\alpha/2} \sqrt{V_1} + z_p \sqrt{V_1}]^2}{\beta^2} \quad (29)$$

Under equal allocation ($p_0 = p_1 = 1/2$), $V_0 < V_1$ and Eq. 27 always yields slightly smaller sample size estimate than the lower sample size bound given in Eq. 20, i.e., $n_{zl} < n_l$.

A similar variation was proposed by Zhu^[17] (method 3 in his study) for NI trials:

$$n_{zl} = \frac{[z_{1-\alpha/2} \sqrt{\tilde{V}_0} + z_p \sqrt{V_1}]^2}{\log^2(M_0 \lambda_0 / \lambda_1)} \quad (30)$$

where $\tilde{V}_0 = (p_0^{-1} + p_1^{-1})\kappa + (p_0 \tilde{\lambda}_0 v_t)^{-1} + (p_1 \tilde{\lambda}_1 v_t)^{-1}$, $\theta = p_1 / p_0$, $a = -\kappa v_t M_0 (1 + \theta)$, $b = \kappa v_t (\lambda_0 M_0 + \theta \lambda_1) - (1 + \theta M_0)$, $c = \lambda_0 + \theta \lambda_1$, and $\tilde{\lambda}_0 = (-b - \sqrt{b^2 - 4ac}) / (2a)$ and $\tilde{\lambda}_1 = M_0 \tilde{\lambda}_0$ are the approximate MLE under $H_0: \lambda_1 = M_0 \lambda_0$.

Zhu^[16] (method 3 in his study) also considered the equivalence trials when $\log(M_u) = -\log(M_l)$. The power can be calculated as:

$$\begin{aligned} &\Phi \left(\frac{\sqrt{n} \left| \log \frac{\lambda_1}{\lambda_0} + \log(M_u) \right| - Z_{\alpha/2} \sqrt{V_0^-}}{\sqrt{V_1}} \right) \\ &+ \Phi \left(\frac{\sqrt{n} \left| \log \frac{\lambda_1}{\lambda_0} + \log(M_u) \right| - Z_{\alpha/2} \sqrt{V_0^+}}{\sqrt{V_1}} \right) - 1 \end{aligned} \quad (31)$$

where $a = -\kappa v_t (1 + \theta) M_l$, $b = \kappa v_t [\lambda_0 M_l + \theta \lambda_1] - (1 + \theta M_l)$, $c = \lambda_0 + \theta \lambda_1$, $\tilde{\lambda}_0 = (-b - \sqrt{b^2 - 4ac}) / (2a)$, $V_0^- = [1 / p_0 + 1 / (p_1 M_l)] / (v_t \tilde{\lambda}_0) + \kappa / (p_0 p_1)$ and V_0^+ can be calculated in the same way with M_l replaced by M_u . Sample size can be calculated by inverting Eq. 31 numerically.

In general, the sample size estimate based on Eqs. 30 and 31 is close to the lower size bound given in Eq. 20 except under extreme parameter configurations.

Cook's Formulae for NI Trials

Cook, Lee, and Li^[18] derived the power formulae for NI trials under the assumption of equal follow-up. The margin is treated as a random quantity in the power calculation.

Sample Size for NI Trials Based on Rate Difference

So far, we assume that the treatment effect is measured by the event rate ratio between two arms. Treatments can also be compared based on the absolute difference in event rates. The choice of the treatment effect metric may depend on the therapeutic areas.^[5] By delta method, Tang^[9] derived the sample size for NI trials:

$$n = \left(\frac{\lambda_0^2}{p_0 d_0} + \frac{\lambda_1^2}{p_1 d_1} \right) \frac{(z_{1-\alpha/2} + z_p)^2}{(\lambda_1 - \lambda_0 - M_{0d})^2} \quad (32)$$

where M_{od} is the NI margin for the absolute rate difference. When the two margins satisfy $M_{od} = \bar{\lambda} \log(M_0)$, Eqs. 32 and 16 generally give close sample size estimates, where $\bar{\lambda} = \sqrt{\lambda_0 \lambda_1}$ is the geometric mean of λ_0 and λ_1 .

Sample Size Under Heterogeneous Dispersion

The power and sample size formulae described in early sections assume a common dispersion parameter across treatment groups. If this assumption does not hold and the dispersion parameter is assumed to vary between groups in the analysis, the power and sample size formulae remain almost unchanged except that one needs to replace κ in d_g , d_{su} , and d_{gl} by the treatment-specific dispersion parameter κ_g .^[9]

Table 1 provides a summary of existing sample size calculation methods for the NB regression by the type of trials and the assumption on the follow-up time.

NUMERICAL ILLUSTRATIONS

We illustrate the performance of several methods using simulation studies. In all cases, the difference in sample size between two arms is 0 or 1 depending on whether the total size n_{tar} is even or odd, and 40,000 trials are generated so that there is about 95% chance that the simulated power is within 0.4% of the true power (standard error $\approx \sqrt{0.8 * 0.2 / 40000} = 0.2\%$).

Table 2 displays the result for superiority trials. For both designs, we set $(\lambda_0, \kappa) = (0.6, 1)$ or $(0.8, 1.2)$ and the RRR to be $1 - \lambda_1 / \lambda_0 = 30\%$ or 50% . The loss to follow-up is exponentially distributed. The simulated power at n_{tar} is close to the 80% nominal power in all cases. Zhu–Lakkis's Eq. 27 yields smaller size estimate than the lower size bound, i.e., $n_{zl} < n_l$. The use of the lower size bound n_l or Zhu–Lakkis estimate by ignoring the variability in the follow-up duration underestimates the required size, and the amount of

Table 1 Summary of existing sample size calculation procedures for the NB regression by the type of trials and the assumption on the follow-up time

(0.6, 0.6)	1.0	1133	1131	1259	1328	79.84
(0.8, 0.8)	1.2	1124	1123	1255	1360	79.89

1) $M_0 = 1/M_1 = 1.3$

2) n_{zl} , n_l , n_{tar} , and n_u are evaluated based on Eqs. 31, 20, 18, and 21, respectively.

3) Data in design 2 are simulated under the assumption of uniform entry.

4) Empirical power is evaluated based on 40,000 simulated trials.

underestimation reaches about 10% in all four cases for design 2. The upper bound n_u only slightly overestimates the required size (by $\leq 2\%$ in all four cases) for design 1.

Table 3 reports the result for NI trials. For both designs, we set $(\lambda_0, \kappa) = (0.6, 1)$ or $(0.8, 1.2)$ and the rate ratio to be $\lambda_1 / \lambda_0 = 60\%$ or 90% . We fix the NI margin for the rate ratio at $M_0 = 1.2$. The performance is similar to that for superiority trials.

Table 4 reports the result for equivalence trials. In both designs, we set $(\lambda_0, \lambda_1, \kappa) = (0.6, 0.6, 1)$ or $(0.8, 0.8, 1.2)$. We fix the margin at $M_u = 1/M_l = 1.3$. The use of the lower size bound n_l or Zhu–Lakkis estimate underestimates the required size.

CONCLUSION

Both theoretical results and simulations confirm that it is necessary to adjust for the between-subject variation in the follow-up time in the power and sample size calculation for comparing two NB rates. Ignoring such variation leads to underpowered trials. One may also use the upper size bound n_u as a slightly conservative size estimate for design 1.

Scaled Average Bioequivalence (SABE)

Laszlo Endrenyi

Department of Pharmacology and Toxicology, University of Toronto, Toronto, Ontario, Canada

Laszlo Tothfalusi

Department of Pharmacodynamics, Semmelweis University, Budapest, Hungary

Abstract

The approach of scaled average bioequivalence (SABE) standardizes, by the within-subject standard deviation, the more frequently applied method of unscaled average bioequivalence. The US Food and Drug Administration recommends that SABE be applied for determining bioequivalence (BE) for drugs that have large within-subject variation and also for those that have a narrow therapeutic index. The European Medicines Agency suggests another procedure for the evaluation of BE of highly variable drug products. Average BE with expanding limits (ABEL) is closely related to SABE and has similar characteristics. Both SABE and ABEL require fewer subjects than unscaled average BE with highly variable drugs. The contribution discusses their background as well as their statistical and regulatory features and presents procedures for their implementation.

Keywords: Bioequivalence; Highly variable drugs; Narrow therapeutic index; Scaled average bioequivalence; Two one-sided tests.

INTRODUCTION

Scaled average bioequivalence (SABE) is an approach for the determination of bioequivalence (BE) of two drug products, which modifies the more frequently applied method of (unscaled) average BE (ABE). Both approaches will be presented in detail. In essence, SABE standardizes the procedure of unscaled ABE by the within-subject standard deviation.

The application of SABE was first recommended for dealing with difficulties encountered when the BE of highly variable (HV) drugs was evaluated.^[1–3] These difficulties arise because the assessment of BE of HV drug products with the regulatory requirements for unscaled ABE cannot in practice be satisfied unless an unethically large number of subjects is enrolled in an investigation.^[4]

The use of SABE has been recently suggested also for the determination of BE of drug products that have a narrow therapeutic index (NTI), those for which there is only small difference between the doses and/or concentrations giving rise to therapeutic and adverse clinical effects.^[5]

Regulatory requirements for unscaled ABE will first be reviewed in this report. It will be followed by the definition and some features of SABE and of a closely related method. Procedures for the implementation of SABE will be summarized. Requirements of various regulatory authorities will then be presented together with their respective merits and disadvantages.

UNSCALED ABE

It is typically expected that the difference between the logarithmic means of relevant pharmacokinetic parameters for the test and reference drug products (μ_T and μ_R) should be between two regulatory limits (θ_1 and θ_2):

$$\theta_1 \leq \mu_T - \mu_R \leq \theta_2 \quad (1)$$

The BE limits are usually symmetrical in the logarithmic scale, $-\theta_1 = \theta_2 = \theta_A$, and therefore,

$$-\theta_A \leq \mu_T - \mu_R \leq \theta_A \quad (2)$$

Regulatory authorities set the value of the BE limit most frequently at $\theta_A = \ln(1.25)$. This corresponds to a geometric mean ratio (*GMR*) between the two formulations:

$$GMR = \exp(\mu_T / \mu_R) = 1.25, \quad (3)$$

i.e., to a 25% difference between the two untransformed means.

BE is tested by two one-sided null hypotheses. They assume the deviation between the logarithmic means is either too low:

$$H_{01} : \mu_T - \mu_R \leq -\theta_A \quad (4a)$$

or too high:

$$H_{02} : \mu_T - \mu_R \geq \theta_A. \quad (4b)$$

The alternative hypotheses represent BE as follows:

$$H_{a1} : \mu_T - \mu_R > -\theta_A \quad (5a)$$

and

$$H_{a2} : \mu_T - \mu_R < \theta_A. \quad (5b)$$

Therefore, BE can be declared if both null hypotheses are rejected in favor of the alternative hypotheses. An operational equivalent of this two one-sided tests (TOST) procedure is

$$-\theta_A \leq \mu_T - \mu_R \leq \theta_A. \quad (2)$$

Consequently, BE can be stated if the confidence interval for the difference between logarithmic means is between the BE limits.^[6,7] Usually, the 90% confidence limits are expected to be between $-\ln(1.25)$ and $+\ln(1.25)$. Thus, not more than a 5% probability is assumed as the Type I error for both null hypotheses.

In practice, the estimated values of the logarithmic means (m_T and m_R) are obtained from the data, and their 90% confidence interval is calculated. For example, in the most frequently performed crossover investigations with two periods and two sequences, the regulatory expectation is

$$-\theta_A \leq (m_T - m_R) \pm t(2s^2/N)^{1/2} \leq \theta_A \quad (6)$$

Here, t is the upper fifth percentile of Student's statistic with $N - 2$ degrees of freedom. N is the number of subjects. s^2 is the residual variation calculated in a relevant analysis of variance; it is related to, but generally not identical with, the within-subject variance.

SABE FOR HV DRUGS

The regulatory model for ABE (Eqs 2 and 5a,b) can be modified by applying a scaling factor (s_w) as follows^[1-3]:

$$-\theta_s \leq (m_T - m_R)/s_w \leq \theta_s. \quad (7)$$

The magnitude of the BE limit (θ_s) is set by the regulatory authorities. s_w is the standard deviation related to the within-subject variation. In two-period crossover investigations, it can be obtained from the residual variation. In studies with three or more periods, the intrasubject variation of one or both drug products can be directly evaluated.

The regulatory expectation of SABE, represented by Eq. 7, is again that its 90% confidence limits should lie within the BE limits of $\pm\theta_s$. Calculation of the BE limits will be summarized later.

The main advantage of SABE is that, for HV drugs, it requires meaningfully fewer subjects for the demonstration of BE compared to unscaled ABE. This is illustrated in Fig. 1. Details of the figure will be presented

later. It shows, under various conditions, the percentage of simulated three-period crossover studies with 24 subjects in which BE was accepted. The power curves were obtained by gradually increasing the *GMR*. At *GMR* = 1.00, the two products are bioequivalent and the highest acceptance is recorded (producer risk). Power curves are presented which are calculated using unscaled ABE and SABE. Acceptances by SABE are substantially higher than those yielded by ABE especially at larger variations. Other conditions shown in Fig. 1 will be described later. The producer risk does not depend on the variation.

SABE has interesting interpretations.^[4] It is an index of standardized effect size^[8] that can measure the importance and significance of clinical effects. It is also widely used in diverse areas of science. SABE is also a distance metric in the function space of probability distributions.^[9] SABE can be derived, with simplifying assumptions, from the regulatory model for individual BE and therefore provides a measure of therapeutic switchability.^[2,10-12]

REGULATORY IMPLEMENTATIONS OF SABE

Regulatory authorities have pursued differing approaches for the implementation of SABE. The approaches of the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) of the European Union have been discussed and compared^[3,13] in Sections "Food and Drug Administration" and "European Medicines Agency."

Both agencies require that the estimated within-subject standard deviation of the reference product (s_{wR}) should be used as the measure of intra-subject variation. Consequently, the regulatory model for the implementation of SABE is

$$-\theta_s \leq (m_T - m_R)/s_{wR} \leq \theta_s. \quad (8)$$

The BE limit (θ_s) is set by the regulatory authorities. It is related to a regulatory constant (σ_0) by

$$\theta_s = \ln(1.25)/\sigma_0. \quad (9)$$

It was recently found^[14] that direct evaluation of Eq. 8 yields biased estimates. The bias could be corrected with Hedges' procedure.^[15] An exact procedure was proposed which is efficient and can be computed easily.^[14]

Food and Drug Administration

The regulatory requirements of the US FDA for the determination of BE of HV drug formulations were presented in a scientific publication.^[3] They were confirmed in more recent publications^[13,14] and a draft guidance.^[13]

The FDA recommends the application of SABE (Eq. 8). In order to obtain the estimated within-subject standard deviation (s_{wR}), the reference formulation should be measured (at least) twice in each subject. Therefore, replicate design studies with either three or four periods should be performed.

GMR limit = 1.25

Fig. 1 Power curves for BE studies, which are evaluated by four methods: unscaled ABE, SABE, the point estimate criterion for *GMR*, and the combination of the SABE and point estimate criteria. The power curves contrast the proportion (in %) of simulated studies in which BE is accepted with increasing *GMR*. The within-subject variation is either 35% (A, C, D) or 60% (B, D and F). EMA requires $CV_s = 30\%$ and $CV_0 = 30\%$ (A and B) whereas FDA expects $CV_s = 30\%$ and $CV_0 = 25\%$ (E and F). Consequences of an unusual switching variation of $CV_s = 25\%$ are illustrated in (C and D)
 Source: [19], with the permission of the publisher.

The FDA suggests $\sigma_0 = 0.25$ (corresponding to a coefficient of variation of $CV_0 = 25\%$) as the value of the regulatory constant, and therefore, $\theta_s = 0.893$.^[3,13,16,17]

By international agreement, a drug is considered to be HV if its within-subject variation is $>30\%$.^[18] Therefore, the FDA recommends that SABE be applied if the observed variation is $>30\%$, whereas ABE be used at lower variations. This is a *mixed regulatory strategy* which uses a switching variation of 30% ($CV_s = 30\%$).

Figure 2 illustrates the strategy. When the recorded intra-subject variation exceeds 30%, the BE limits,

evaluated with ABE, widen with increasing s_{WR} . When the within-subject variation is not $>30\%$, the BE limits remain constant at $\pm \ln(1.25)$. Figure 2B shows that the strategy results in discontinuous (implied) BE limits because the switching variation is 30%, different from the stated regulatory constant of $\sigma_0 = 0.25$.^[2,19]

FDA suggests that, in order to calculate the confidence limits, the SABE model (Eq. 8) be squared and then linearized:

$$(m_T - m_R)^2 - \theta_s^2 \cdot s_{WR}^2 \leq 0. \quad (10)$$

Fig. 2 Mixed regulatory model for the determination of BE of HV drugs. Thick lines show the logarithmic BE limits. They have a constant level of $\pm \ln(1.25)$, and unscaled ABE is applied, when the within-subject variation (CV_w) does not exceed 30%. The limits widen at higher variations and either SABE or ABEL is applied. The slope of the expansion (in the logarithmic scale) is determined by a regulatory constant which corresponds to a standardized variation (CV_0). (A) According to the requirement of EMA, $CV_0 = 30\%$; the BE limits are continuous. (B) Following the expectation of FDA, $CV_0 = 25\%$; the BE limits are discontinuous around $CV_w = 30\%$. Source: Endrenyi and Tothfalusi,^[19] with the permission of the publisher.

The 95% upper bound can be calculated from the distributions of the two components.^[20,21] BE is accepted if the upper bound is zero or negative and rejected if it is positive. The procedure was implemented in a SAS program and published in a draft guidance of FDA.^[22] However, the procedure has a small bias, which should be taken into account in regulatory considerations.^[14] The computer program also has some difficult features including instability with the partial replicate design and the need for balanced data; the latter requirement was analyzed and criticized.^[23]

For the determination of the BE of HV drug products, the FDA requires also that the point estimate of *GMR* be between 0.80 and 1.25.^[3,13,16,17] This expectation is additional to that based on SABE and introduces awkward complications.^[19]

European Medicines Agency

The approach of EMA for the determination of BE for HV drugs^[24] differs from that of FDA, but the two procedures are closely related. The SABE model (Eq. 8) is rearranged:

$$-\theta_A = -\theta_s * s_{WR} \leq m_T - m_R \leq \theta_s * s_{WR} = \theta_A. \quad (11)$$

Consequently, the BE limits widen in proportion to the estimated within-subject variation of the reference product. Boddy et al.^[25] first recommended this approach of ABE with expanding limits (ABEL).

EMA recommends the BE limit of $\theta_s = 0.760$, and, therefore, the regulatory constant of $\sigma_0 = 0.294$, in applying the ABEL approach.^[24] These regulatory definitions enable

the continuity of the BE limits at the switching variation of $CV_s = 30\%$ (Fig. 2A).^[19]

The approaches of SABE and ABEL are functionally identical and yield closely similar results. ABEL is actually ABE, and, therefore, the confidence limits can be calculated by the simple TOST procedure (as for Eqs 2 and 6); for a statement of BE, the 90% confidence limits are expected to be between the BE limits of $\pm \theta_A$. However, the BE limits of ABEL are random variables; this could be of limited concern which diminishes as the sample size increases. Even a typical study sample of 24 subjects yields satisfactorily robust estimates.

EMA also requires, in addition to the ABEL criterion, that the point estimate of *GMR* be between 0.80 and 1.25. Moreover, the BE limits may be widened only up to a variation of 50%. At higher variations, the limits should remain restricted to $\pm \ln(1.43)$. Furthermore, application of ABEL is limited to only one of the main pharmacokinetic parameters (maximum concentration, C_{max}) but not allowed for the other (area under the concentration–time curve or AUC).^[24]

Comparison of the Approaches of FDA and EMA

The procedures recommended by FDA and EMA for the determination of BE of HV drug products are similar in many respects. Most importantly, they utilize either SABE or an approach closely related to it, ABEL. The two procedures (Eqs 8 and 11) transform into each other. They apply the mixed regulatory strategy which starts to apply SABE or ABEL at a variation of 30%. They impose also

a secondary regulatory criterion that constrains the point estimate of *GMR*.

However, there are meaningful differences in the implementations of the two approaches. The confidence limits for SABE are evaluated from its squared and linearized form (Eq. 10).^[21] A specialized computer program, such as presented by the FDA,^[22] is needed for its calculation. In contrast, the confidence limits for ABEL are obtained by the customary TOST procedure. This appears to be simpler and easier to visualize and interpret.

The FDA and EMA recommend differing values of the regulatory constant σ_0 , 0.25 and 0.294, respectively. The resulting BE limits are $\theta_s = 0.893$ and 0.759, respectively. The differing conditions have important effects.

Figure 2 illustrates that the BE limits are continuous with the constant suggested by EMA around the variation of $CV = 30\%$ (Fig. 2A) but discontinuous with the value proposed by the FDA (Fig. 2B).

Discontinuity has regrettable consequences. First, it gives rise to regulatory uncertainty: the BE limits are strongly different depending on whether the estimated within-subject variation is, e.g., 29% or 31%. Second, the sample size required for pursuing a BE investigation with sufficient power is continuous with the regulatory constant suggested by EMA but discontinuous when the recommendation of FDA is followed.^[19]

The Type I error (i.e., the “consumer risk” of accepting BE when it is actually incorrect) is inflated around the switching variation ($CV_s = 30\%$). The inflation is much higher, almost 15%, with $\sigma_0 = 0.25$ as the value of the regulatory constant than with $\sigma_0 = 0.294$ which yields an inflation to about 7% (Table 1), thereby preferring the recommendation of EMA to that of the FDA.^[19] This observation was recently confirmed.^[26]

The inflation of the Type I error around $CV = 30\%$ is a consequence of the mixed regulatory strategy. Assume, as an illustration, that the true within-subject variation of

a drug is 29%, i.e., that it is not HV. Nevertheless, its variation could be by chance, say, 32% in a given investigation, thereby classifying the drug as being HV. Figure 2 illustrates that the BE limits would then be wider and the probability of acceptance higher. Thus, the risk of false acceptance would be $>5\%$. The risk is seen to be larger when $\sigma_0 = 0.25$ than when $\sigma_0 = 0.294$ (Fig. 2A vs. 2B).^[19]

The issue of the inflation of the Type I error has been controversial, but the observation has been further confirmed.^[27,28]

Moreover, when $\sigma_0 = 0.25$ and at high variation, the joint decision based on both the SABE confidence criterion and the *GMR* constraint is essentially that of the *GMR* constraint and not of the SABE criterion (Fig. 1D and 1F). This is a misleading and unfortunate situation. With $\sigma_0 = 0.294$, the influence of the SABE criterion is maintained much more effectively (Fig. 1B).

Application of SABE lowers the sample sizes needed for the determination of BE in comparison with the use of the usual, unscaled approach.^[29] Sample sizes required for the expectations of the FDA and EMA and with three- and four-period study designs are available at various within-subject variations.^[29] Fewer subjects are required by the FDA than by the EMA procedure. The additional requirements by the two regulatory agencies raise the required number of subjects.

SABE FOR NTI DRUGS

The FDA has recently recommended that SABE be used for the evaluation of BE for some drugs such as warfarin and tacrolimus which have an NTI.^[30] According to one definition, with NTI drugs “small differences in dose or blood concentration may lead to serious therapeutic failures and/or adverse drug reactions.”^[5]

The FDA suggests that the SABE model (Eq. 8) be applied with a regulatory constant of $\sigma_0 = 0.10$. The BE limit is defined now as

$$\theta_s = \ln(1.1111)/\sigma_0 = 1.0536, \quad (12)$$

noting that $1/0.90 = 1.1111$.^[30,31]

In order to obtain the estimated standard deviation of the reference product, four-way, fully replicated crossover investigations should be performed.

The 95% upper confidence bound should be calculated again from the transformation in Eq. 10.

The FDA recommends also additional conditions.^[30,31] First, the BE limits should not be wider than the usual range of 80%–125%. Therefore, the BE limits gradually widen with increasing within-subject variation until this reaches $CV = 21.4\%$ but remain at their constant range thereafter (Fig. 3).^[32] Therefore, the FDA proposes that the confidence interval be estimated by unscaled ABE, and that the results of a study be presented by either unscaled

Table 1 Consumer risk for the determination of BE

Mixed strategy	Regulatory standardized variation (%)	Consumer risk (%)		
		Unscaled ABE	SABE	
			Without <i>GMR</i> constraint	With <i>GMR</i> constraint
No	30	4.95	5.56	5.56
No	25	4.98	16.50	16.34
Yes	30	5.01	6.98	6.98
Yes	25	4.94	14.78	14.61

Switching variation: $CV_s = 30\%$;

Within-subject variation: $CV_w = 30\%$;

Constraint on point estimate = 25% ($GMR = 1.25$);

For the regulatory standardized variation (CV_0), corresponding to the assumed regulatory constant (σ_0), either 25% (the expectation of FDA) or 30% (the requirement of EMA) was considered. The computations were performed with or without the use of the mixed regulatory strategy, and with or without the constraint of $GMR = 1.25$. *GMR*: geometric mean ratio.

Fig. 3 BE limits for drugs with NTI. SABE is applied and the corresponding implied BE limits widen when the within-subject variation of the reference product (CV_{WR}) increases until it reaches 21.4%. The BE limits remain constant between 80% and 125%, and unscaled ABE is applied when the variation is higher

Source: Endrenyi and Tothfalusi,^[19] with the permission of the publisher.

ABE or SABE depending on whether calculated BE does not or does exceed the 80%–125% range.

The FDA suggests also that a second test be performed that compares the within-subject variances of the two drug products. By applying an F -test, the 90% upper limit for the test/reference variance ratio should not be higher than 6.25.^[30,31]

It is not known how the additional conditions suggested by the FDA affect the performance of primary test involving the confidence limits for SABE.

CONCLUSIONS

SABE is a valuable and useful approach for evaluating the BE of drug products under certain special circumstances. When a drug has large within-subject variation, SABE enables a substantial increase in power and a reduction in the number of subjects required for an effective investigation (Fig. 1).

The FDA recommends the model of SABE (Eq. 8) with a regulatory constant of $\sigma_0 = 0.25$ for the analysis of HV drugs. However, this constant results in a discontinuity of the BE limits and a higher Type I error around $CV = 30\%$ (Fig. 2B) as well as in larger regulatory uncertainty. The confidence bound for the relative pharmacokinetic parameters is calculated from a transformed form of the model (Eq. 10) by using specialized computer programs. Evaluation of SABE yields biased estimates which is sample size dependent for the FDA method and can be easily corrected for the exact approach.^[14]

EMA proposes that ABEL (Eq. 11), a procedure closely related to and a transformation of SABE, be used

with a regulatory constant of $\sigma_0 = 0.294$. The BE limits are continuous around $CV = 30\%$ and the usual TOST procedure can be utilized for calculating the confidence limits.

Both the FDA and EMA impose additional regulatory expectations that may modify the performance of the primary requirement, which involves the confidence limits for the comparative parameters.

The FDA also suggests that SABE be applied to the determination of BE for drugs which have an NTI. In this case, $\sigma_0 = 0.10$ is proposed. The expansion of the BE limits is recommended until a range of 80%–125% is reached (Fig. 3).

Screening Design

John R. Murphy

Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

Abstract

A “screening design” refers to an experimental design that is applicable when a large number of potential causative factors need to be examined to find the most important few that may have an effect on one or more responses of interest. This brief entry provides an illustrated definition of screening design.

INTRODUCTION

A “screening design” refers to an experimental design that is applicable when a large number of potential causative factors need to be examined to find the most important few that may have an effect on one or more responses of interest. Screening designs may be derived from highly fractionated factorial designs and are called “orthogonal main effect plans” or “orthogonal arrays,” because main effects and only a few two-factor interactions are unconfounded with one another. Effects are confounded when the contrasts for estimating them are not orthogonal, and effects are completely confounded when their contrasts are identical. Plackett and Burman^[1] devised orthogonal arrays useful for screening that yield unbiased estimates of all main effects in the smallest design possible. For example, up to 11 factors can be screened in a 12-run Plackett–Burman design. Examples of 8-run and 12-run Plackett–Burman designs are provided in [Tables 1](#) and [2](#), respectively. Interest in using screening designs in industrial settings has increased in recent years due partly to the work of Taguchi,^[2] a Japanese engineer who promoted the use of

designs he termed orthogonal arrays, many of which are similar to Plackett–Burman designs.

The most obvious criticism of screening designs is that they allow at most a small subset of the interactions to be estimated. Interactions can sometimes be more important than main effects for understanding or modeling the process under study. For this reason, many experts in the field recommend sequential experimentation, in which screening is followed by one or more experimental designs using fewer factors, such as larger fractions of factorial designs, central composite designs, or Box–Behnken designs, that permit estimation of interaction and/or curvature. Proponents of the Taguchi designs have favored a slightly different philosophy about screening designs, where the experiment is considered more of a “one-shot,” “pick-the-winner” approach to identify the optimal settings of the factors, followed up by several confirmatory runs at the predicted optimum.

CONCLUSION

In the pharmaceutical industry, the most concentrated use of screening designs, factorial designs, and response surface designs is found in the product and process development functions, including analytical method development, because of the increasing complexity in the optimization and validation of analytical methods. In the evolving environment of rapid and shortened development cycles, screening designs and experimental design in general

will continue to gain acceptance as valuable development tools.

Seamless Adaptive Trial Design: Dose Selection Criteria

Jiayin Zheng and Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

In pharmaceutical/clinical development, commonly considered two-stage seamless adaptive designs include a two-stage phase I/II or phase II/III adaptive trial that combines one phase IIb study for dose finding or treatment selection and one phase III study for efficacy confirmation into a single study. At the end of stage 1, promising dose(s) will be selected based on pre-specified selection criteria. In practice, since there is little power with limited subjects available at interim, commonly considered selection criteria for critical decision-making include (i) conditional power, (ii) precision analysis, (iii) predictive probability of success, and (iv) probability of being the best dose or treatment. The selected promising dose(s) will then proceed to the next stage for efficacy confirmation. In this article, we introduce, compare, and evaluate these criteria. Besides, we attempt to address some concerns for two-stage seamless adaptive clinical trial.

Keywords: Dose selection; Efficacy; Interim analysis; Probability of being the best dose; Seamless adaptive design.

INTRODUCTION

In pharmaceutical/clinical development, a two-stage seamless adaptive trial design that combines two individual studies into a single study is often considered. Commonly considered two-stage seamless adaptive designs include a two-stage phase I/II or phase II/III adaptive trial that combines one phase IIb study for dose finding or treatment selection and one phase III study for efficacy confirmation into a single study. Thus, a two-stage seamless adaptive trial design consists of two stages: dose finding or treatment selection (stage 1) and efficacy confirmation (stage 2). The study objective at the first stage is for dose finding or treatment selection, whereas the study objective at stage 2 is to confirm the efficacy of the dose or treatment selected from the first stage compared to a control (dose or treatment). If the study endpoints employed at different stages are the same, the two-stage seamless adaptive trial design lead to a typical two-stage adaptive design with different study objectives at different stages as described in the work of Chow and Lin.^[1]

For a two-stage seamless adaptive trial design, at the first stage, qualified subjects are usually randomly assigned to receive a dose or treatment at a 1:1 ratio. At the end of stage 1, promising dose(s) will be selected based on pre-specified selection criteria. In practice, since there is little power with limited subjects available at interim, commonly considered selection criteria for critical decision-making include (i) precision analysis,

(ii) predictive probability of success, and (iii) probability of being the best dose or treatment.^[1,2] The selected promising dose(s) will then proceed to the next stage for efficacy confirmation. Based on the results observed at interim, some adaptations such as adaptive randomization or sample size re-estimation are often applied for achieving the study objectives and/or increasing the probability of success.

In practice, for clinical studies utilizing two-stage seamless adaptive trial designs, the following questions are commonly asked by the regulatory agencies such as the United States Food and Drug Administration. First, it is a concern whether the overall type I error rate is well controlled at a pre-specified level of significance. Second, it is a concern that the selection criteria at stage 1 may wrongly select inferior dose groups based on the limited number of subjects available at interim. Third, it is a concern that the interim data may deviate far from expected (i.e., the assumptions made at the beginning of study). In this research, we attempt to address these concerns for two-stage seamless adaptive clinical trial.

Criteria that are commonly employed for dose selection at the first stage are briefly described in Section “Criteria for Dose Selection.” The performances of these selection criteria in terms of the coverage probability of correctly selecting the promising dose(s) are evaluated through the conduct of extensive clinical trial simulation in Section “Practical Implementation and Example.” Section “Simulation Studies” illustrates the application of these selection

criteria based on single primary study endpoint as well as co-primary study endpoints. Concluding remarks are given in Section “Conclusion.”

CRITERIA FOR DOSE SELECTION

Consider the dose-finding stage in a clinical trial. Assume there are k test doses and one control dose to investigate in this stage. Denote the measurement means corresponding to the k doses by $D_1, D_2, \dots, D_k$ and that of the control dose by D_0 . We are interested in the difference $d_i = D_i - D_0$, $i = 1, \dots, k$. Without generality, assume the larger of this difference, the better effect of the corresponding dose. Denote X_{ij} , $i = 0, 1, \dots, k$, $j = 1, \dots, N_i$, where N_i is the sample size of the i th dose, as the measurement of the j th subject with the i th dose. For each dose, assume X_{ij} , $j = 1, \dots, N_i$ are independent and identically distributed, and follow a normal distribution with an unknown mean D_i and an unknown

where $q_{\alpha/2}$ is the upper $\alpha/2$ quantile of the standard normal distribution and the pooled sample standard deviation

$$\tilde{S}_i' = \sqrt{\frac{(n_i - 1)S_i'^2/n_i + (n_0 - 1)S_0'^2/n_0}{n_i + n_0 - 2}}.$$

Conditional Power

At interim, denote the observed effect size by

$$\hat{\delta}_i' = \frac{\bar{X}_i' - \bar{X}_0'}{\sqrt{S_i'^2 + S_0'^2}} \text{ for dose } i.$$

Take $\hat{\delta}_i'$ (or $(\bar{X}_i', \bar{X}_0', S_i'^2, S_0'^2)$) as the true value of the effect size (or means of dose i and control dose, and variances of dose i and control dose, respectively), and calculate the power with the pre-specified sample size, denoted as p_i^{power} . p_i^{power} can be expressed as

$$pr \left\{ \frac{\bar{X}_i' - \bar{X}_0'}{\sqrt{\frac{(N_i - 1)S_i'^2}{N_i} + \frac{(N_0 - 1)S_0'^2}{N_0}}} > q_{\alpha} \mid (D_i, D_0, \sigma_i^2, \sigma_0^2) = (\bar{X}_i', \bar{X}_0', S_i'^2, S_0'^2) \right\},$$

variance σ_i^2 . Denote $\bar{X}_i$ as the sample mean and S_i^2 as the sample variance for dose i . Based on the total sample size of $N = \sum_{i=1}^k N_i$, we can construct the $1 - \alpha$ confidence interval of the mean d_i as follows:

$$(L_i, U_i) = (\bar{X}_i - \bar{X}_0 - q_{\alpha/2} \tilde{S}_i, \bar{X}_i - \bar{X}_0 + q_{\alpha/2} \tilde{S}_i),$$

where $q_{\alpha/2}$ is the upper $\alpha/2$ quantile of the standard normal distribution and the pooled sample standard deviation

$$\tilde{S}_i = \sqrt{\frac{(N_i - 1)S_i^2/N_i + (N_0 - 1)S_0^2/N_0}{N_i + N_0 - 2}}.$$

Assume that at interim, the data from $n = \sum_{i=1}^k n_i$ subjects are available, with n_i subjects available for each dose. Denote $\bar{X}_i'$ as the sample mean and $S_i'^2$ as the sample variance for dose i at interim. Then similarly, we have the $1 - \alpha$ confidence interval of the mean d_i :

$$(L_i', U_i') = (\bar{X}_i' - \bar{X}_0' - q_{\alpha/2} \tilde{S}_i', \bar{X}_i' - \bar{X}_0' + q_{\alpha/2} \tilde{S}_i'),$$

where q_{α} is the upper α quantile of the standard normal distribution. Noncentral t distribution can be used to calculate this probability.

Select the dose with the largest p_i^{power} . If $N_i, i = 0, 1, \dots, k$ are equal, then this criterion is equivalent to choosing the one having the largest observed effect size $\hat{\delta}_i'$.

Precision Analysis Based on Confidence Interval

Denote (L_i^+, U_i^+) as the positive part of (L_i', U_i') . Define $p_i^+ = pr\{d_i \in (L_i^+, U_i^+)\}$ as the confidence level for achieving statistical significance. If $L_i' \geq 0$, $p_i^+ = 1 - \alpha$. If $U_i' < 0$, $p_i^+ = 0$. If (L_i', U_i') contains 0, then $p_i^+ = pr\{d_i \in (0, U_i')\}$, and we derive the exact expression of p_i^+ in this case. Denote

$w_i = \Phi\left(\frac{\bar{X}_i' - \bar{X}_0'}{\tilde{S}_i'}\right)$, where Φ is the cumulative distribution function of standard normal distribution. Then $p_i^+ = w_i - \alpha/2$.

Based on $p_i^+, i = 1, \dots, k$, select the dose having the highest p_i^+ .

Predictive Probability of Success

Assume that the difference observed at interim, $\bar{X}_i', i = 1, \dots, k$, preserved to the end of the study. We calculate

the predictive probability of success $pr\{d_i > d\}$ at interim, where d is a prespecified value. Denote $p_i^s = pr\{d_i > d\}$. We have the mean difference $\bar{X}_i - \bar{X}_0$ and the pooled sample standard deviation

$$\tilde{S}_i^p = \sqrt{\frac{(N_i - 1)S_i'^2/N_i + (N_0 - 1)S_0'^2/N_0}{N_i + N_0 - 2}}$$

based on the data obtained at interim. Then

$$p_i^s = \Phi\left(\frac{\bar{X}_i' - \bar{X}_0' - d}{\tilde{S}_i^p}\right),$$

$$p_i^{\text{power}} = pr\left\{\frac{\bar{X}_i - \bar{X}_0}{\sqrt{\frac{(N_i - 1)S_i^2}{N_i} + \frac{(N_0 - 1)S_0^2}{N_0}}} > q_\alpha \mid (D_i, D_0, \sigma_i^2, \sigma_0^2) = (\bar{X}_i', \bar{X}_0', S_i'^2, S_0'^2)\right\}.$$

where Φ is the cumulative distribution function of standard normal distribution. We may select the dose with the highest p_i^s .

Probability of Being the Best Dose

Calculate $p_i^b = pr\{\max_i(d_i) = d_i\}$, which is the probability of being the best dose, based on the interim data. Taking $X_{0j}, j = 1, \dots, N_0$, as fixed values, we can assume $(\bar{X}_i, S_i^2)$ is statistically independent with $(\bar{X}_{i_2}, S_{i_2}^2)$ for any $i_1 > i_2$. It also holds for

$$(\bar{X}_i', S_i'^2), i = 1, \dots, k.$$

We have

$$p_i^b = \int \frac{1}{\tilde{S}_i'} \phi\left(\frac{z - (\bar{X}_i' - \bar{X}_0')}{\tilde{S}_i'}\right) \prod_{g=1, i \neq g}^k \Phi\left(\frac{z - (\bar{X}_g' - \bar{X}_0')}{\tilde{S}_g'}\right) dz,$$

where ϕ and Φ are the probability density function and the cumulative distribution function of standard normal distribution, respectively. Similar to the predictive probability of success, $\tilde{S}_i'$ and $\tilde{S}_g'$ in the above expression of p_i^b can be replaced with $\tilde{S}_i^p$ and $\tilde{S}_g^p$.

Thus, we may select the dose with the largest p_i^b .

PRACTICAL IMPLEMENTATION AND EXAMPLE

In this section, we describe the practical implementation under the case of single primary endpoint and the case of co-primary endpoint. A real example will be given to illustrate these methods.

Single Primary Endpoint

As introduced in the previous section, we summarize the criteria for dose selection under the case of single primary endpoint as follows:

Conditional power—Select the dose having the largest p_i^{power} .

Precision analysis based on confidence interval—Select the dose having the highest p_i^* : if $L_i' \geq 0$, $p_i^* = 1 - \alpha$; if

$$U_i' < 0, p_i^* = 0; \text{ if } (L_i', U_i') \text{ contains } 0, p_i^* = \Phi\left(\frac{\bar{X}_i' - \bar{X}_0'}{\tilde{S}_i'}\right)$$

$$- \alpha/2, \text{ where } \tilde{S}_i' = \sqrt{\frac{(n_i - 1)S_i'^2/n_i + (n_0 - 1)S_0'^2/n_0}{n_i + n_0 - 2}}.$$

Predictive probability of success—Select the dose

with the highest p_i^s : $p_i^s = \Phi\left(\frac{\bar{X}_i' - \bar{X}_0' - d}{\tilde{S}_i^p}\right)$, where

$$\tilde{S}_i^p = \sqrt{\frac{(N_i - 1)S_i'^2/N_i + (N_0 - 1)S_0'^2/N_0}{N_i + N_0 - 2}} \text{ and } d \text{ is a pre-}$$

specified value.

Probability of being the best dose—Select the dose with the largest p_i^b :

$$p_i^b = \int \frac{1}{\tilde{S}_i'} \phi\left(\frac{z - (\bar{X}_i' - \bar{X}_0')}{\tilde{S}_i'}\right) \prod_{g=1, i \neq g}^k \Phi\left(\frac{z - (\bar{X}_g' - \bar{X}_0')}{\tilde{S}_g'}\right) dz.$$

Co-primary Endpoints

Assume under the case of co-primary endpoint, the type I error allocated to each endpoint is equal (i.e., $\alpha/2$). Denote the measurement means corresponding to the k doses by $D_1, D_2, \dots, D_k$, and that of the control dose by D_0 for the first

endpoint. Similarly, denote those for the second endpoint by $E_1, E_2, \dots, E_k$ and E_0 . We are interested in the differences $d_i = D_i - D_0$ and $g_i = E_i - E_0$, $i = 1, \dots, k$. Without generality, assume the larger this difference, the better effect of the corresponding dose. Denote X_{ij} , $i = 0, 1, \dots, k$, $j = 1, \dots, N_i$, where N_i is the sample size of the i th dose, as the measurement of the j th subject with the i th dose for the first endpoint. Similarly, denote Y_{ij} as the measurement of the j th subject with the i th dose for the second endpoint. For each dose, assume X_{ij} , $j = 1, \dots, N_i$ are independent and identically distributed, and follow a normal distribution with an unknown mean D_i and an unknown variance σ_{1i}^2 . Similarly, assume Y_{ij} , $j = 1, \dots, N_i$ are independent and identically distributed, and follow a normal distribution with an unknown mean E_i and an unknown variance σ_{2i}^2 . Denote $\bar{X}_i$ and $\bar{Y}_i$ as the sample means and S_i^2 and Q_i^2 as the sample variances for dose i . Based on the total sample size of $N = \sum_{i=1}^k N_i$, we can construct the $1 - \alpha$ confidence intervals of the mean d_i and g_i as follows:

$$(L_{1i}, U_{1i}) = (\bar{X}_i - \bar{X}_0 - q_{\alpha/2} \tilde{S}_i, \bar{X}_i - \bar{X}_0 + q_{\alpha/2} \tilde{S}_i),$$

$$(L_{2i}, U_{2i}) = (\bar{Y}_i - \bar{Y}_0 - q_{\alpha/2} \tilde{Q}_i, \bar{Y}_i - \bar{Y}_0 + q_{\alpha/2} \tilde{Q}_i),$$

Assume that at interim, the data from $n = \sum_{i=1}^k n_i$ subjects are available, with n_i subjects available for each dose. Denote $\bar{X}'_i$ and $\bar{Y}'_i$ as the sample means and $S_i'^2$ and $Q_i'^2$ as the sample variances for dose i at interim. Then similarly, we have the $1 - \alpha$ confidence interval of the means d_i and g_i

$$(L'_{1i}, U'_{1i}) = (\bar{X}'_i - \bar{X}'_0 - q_{\alpha/2} \tilde{S}'_i, \bar{X}'_i - \bar{X}'_0 + q_{\alpha/2} \tilde{S}'_i),$$

$$(L'_{2i}, U'_{2i}) = (\bar{Y}'_i - \bar{Y}'_0 - q_{\alpha/2} \tilde{Q}'_i, \bar{Y}'_i - \bar{Y}'_0 + q_{\alpha/2} \tilde{Q}'_i),$$

where $q_{\alpha/2}$ is the upper $\alpha/2$ quantile of the standard normal distribution and the pooled sample standard deviations

$$\tilde{S}'_i = \sqrt{\frac{(n_i - 1)S_i'^2/n_i + (n_0 - 1)S_0'^2/n_0}{n_i + n_0 - 2}} \text{ and}$$

$$\tilde{Q}'_i = \sqrt{\frac{(n_i - 1)Q_i'^2/n_i + (n_0 - 1)Q_0'^2/n_0}{n_i + n_0 - 2}}.$$

Then we have the criteria for dose selection under the case of co-primary endpoint as follows:

Conditional power—Select the dose with the largest p_i^{power} .

$$p_i^{\text{power}} = \left\{ \begin{array}{l} \frac{\bar{X}_i - \bar{X}_0}{\sqrt{\frac{(N_i - 1)S_i^2 + (N_0 - 1)S_0^2}{N_i + N_0 - 2}}} > q_{\alpha/2}, \frac{\bar{Y}_i - \bar{Y}_0}{\sqrt{\frac{(N_i - 1)Q_i^2 + (N_0 - 1)Q_0^2}{N_i + N_0 - 2}}} > q_{\alpha/2} \\ \left| (D_i, D_0, \sigma_{1i}^2, \sigma_{10}^2) = (\bar{X}'_i, \bar{X}'_0, S_i'^2, S_0'^2), (E_i, E_0, \sigma_{2i}^2, \sigma_{20}^2) = (\bar{Y}'_i, \bar{Y}'_0, Q_i'^2, Q_0'^2) \right\} \end{array} \right.$$

where $q_{\alpha/2}$ is the upper $\alpha/2$ quantile of the standard normal distribution and the pooled sample standard deviations

$$\tilde{S}_i = \sqrt{\frac{(N_i - 1)S_i^2/N_i + (N_0 - 1)S_0^2/N_0}{N_i + N_0 - 2}} \text{ and}$$

$$\tilde{Q}_i = \sqrt{\frac{(N_i - 1)Q_i^2/N_i + (N_0 - 1)Q_0^2/N_0}{N_i + N_0 - 2}}.$$

Precision analysis based on confidence interval—Select the dose having the highest p_i^+ :

$$\begin{aligned} p_i^+ &= \text{pr}\{d_i \in (L_{1i}^+, U_{1i}^+), g_i \in (L_{2i}^+, U_{2i}^+)\} \\ &= \text{pr}\{d_i \in (\max(0, L_{1i}^+), \max(0, U_{1i}^+)), \\ &\quad g_i \in (\max(0, L_{2i}^+), \max(0, U_{2i}^+))\}, \end{aligned}$$

where (L_{1i}^+, U_{1i}^+) and (L_{2i}^+, U_{2i}^+) as the positive parts of (L_{1i}', U_{1i}') and (L_{2i}', U_{2i}') , respectively. Under the assumption of the statistical independence between X_{ij} and Y_{ij} , we can express p_i^+ in detail as follows:

If $L_{2i}' \geq 0$, and $L_{1i}' \geq 0$, $p_i^+ = (1 - \alpha)^2$.

If $L_{2i}' \geq 0$ and (L_{1i}', U_{1i}') contains 0, $p_i^+ = (1 - \alpha)^* \left(\Phi \left(\frac{\bar{X}_i' - \bar{X}_0'}{\tilde{S}_i'} \right) - \alpha/2 \right)$, where

$$\tilde{S}_i' = \sqrt{\frac{(n_i - 1)S_i'^2/n_i + (n_0 - 1)S_0'^2/n_0}{n_i + n_0 - 2}}.$$

If $L_{1i}' \geq 0$ and (L_{2i}', U_{2i}') contains 0, $p_i^+ = (1 - \alpha)^* \left(\Phi \left(\frac{\bar{Y}_i' - \bar{Y}_0'}{\tilde{Q}_i'} \right) - \alpha/2 \right)$, where

$$\tilde{Q}_i' = \sqrt{\frac{(n_i - 1)Q_i'^2/n_i + (n_0 - 1)Q_0'^2/n_0}{n_i + n_0 - 2}}.$$

If both (L_{1i}', U_{1i}') and (L_{2i}', U_{2i}') contain 0, $p_i^+ = \left(\Phi \left(\frac{\bar{X}_i' - \bar{X}_0'}{\tilde{S}_i'} \right) - \frac{\alpha}{2} \right) * \left(\Phi \left(\frac{\bar{Y}_i' - \bar{Y}_0'}{\tilde{Q}_i'} \right) - \frac{\alpha}{2} \right)$.

Otherwise, $p_i^+ = 0$.

Predictive probability of success—Select the dose with the highest p_i^s : $p_i^s = pr\{d_i > d, g_i > g\}$. Under the assumption of the statistical independence between X_{ij} and Y_{ij} , we can express

$$p_i^s = \Phi \left(\frac{\bar{X}_i' - \bar{X}_0' - d}{\tilde{S}_i^p} \right) \Phi \left(\frac{\bar{Y}_i' - \bar{Y}_0' - g}{\tilde{Q}_i^p} \right)$$

where $\tilde{S}_i^p = \sqrt{\frac{(N_i - 1)S_i'^2/N_i + (N_0 - 1)S_0'^2/N_0}{N_i + N_0 - 2}}$, $\tilde{Q}_i^p = \sqrt{\frac{(N_i - 1)Q_i'^2/N_i + (N_0 - 1)Q_0'^2/N_0}{N_i + N_0 - 2}}$, and d, g are prespecified values.

Probability of being the best dose—Select the dose with the largest p_i^b :

$$\begin{aligned} p_i^b &= pr\{max_i(d_i) = d_i, max_i(g_i) = g_i\} \\ &= \int \frac{1}{\tilde{S}_i'} \phi \left(\frac{z - (\bar{X}_i' - \bar{X}_0')}{\tilde{S}_i'} \right) \prod_{g=1, i \neq g}^k \Phi \left(\frac{z - (\bar{X}_g' - \bar{X}_0')}{\tilde{S}_g'} \right) dz, \\ &\quad \int \frac{1}{\tilde{Q}_i'} \phi \left(\frac{w - (\bar{Y}_i' - \bar{Y}_0')}{\tilde{Q}_i'} \right) \prod_{h=1, i \neq h}^k \Phi \left(\frac{w - (\bar{Y}_h' - \bar{Y}_0')}{\tilde{Q}_h'} \right) dw, \end{aligned}$$

under the assumption of the statistical independence between X_{ij} and Y_{ij} .

An Example

A clinical study was intended to be designed as a two-stage phase II/III seamless, adaptive, randomized, double-blind, parallel-group, placebo-controlled, multicenter study to evaluate the efficacy, safety, and dose-response of a compound in treating postmenopausal women and adjuvant breast cancer patients with vasomotor symptoms (VMSs). VMSs are often referred to as hot flashes, flushes, and night sweats, sometimes accompanied by shivering and a sense of cold. The primary study endpoints would be frequency and severity of VMS evaluated at weeks 4 and 12 as co-primary endpoints. Since the real data for this study are unavailable, we provide this example with numerical simulated data to illustrate the use of the dose-selection methods, based on such studies.

Under this two-stage adaptive trial design, the first stage is a phase II trial for dose selection. The second stage is a phase III trial for confirming the efficacy and safety of the compound. An interim analysis will be conducted to evaluate the dose effect and to review the efficacy and safety effects when about 50% subjects at stage 1 complete week 4 of double-blind treatment period. One or two optimal dose(s) will be selected and the sample size will be reestimated. The second stage of the study starts after the interim analysis. Newly enrolled subjects will be randomized to receive the selected optimal dose(s) or placebo for 12 weeks. The second stage will serve as a pivotal study.

For frequency, at week 4, each study subject reported the number of VMSs each day, and those numbers were averaged for each subject. For severity, each subject was asked to rate how much they were bothered by VMS at the end of week 4 using scores from 1 to 10 with higher value indicating more severity. Three doses and one placebo were compared. Eight hundred subjects were recruited into the study with 200 in each group. At interim, each group had 100 subjects having completed week 4 of the treatment period. The logarithm transformation of frequency and the original scale of severity were treated as following normal distributions and were used for interim analysis. Using the method of probability of being the best dose, which was shown to be the best one in the simulation studies, we selected dose 3, which had the largest overall probability of being the best dose. The results were shown with means and variances of the two co-primary endpoints.

SIMULATION STUDIES

In this section, we conducted the simulation studies to investigate the performances of the four methods described in Section “Criteria for Dose Selection.”

Single Primary Endpoint

Assume the mean effects of four doses (dose 1 as the placebo) are to be compared, and all effects follow normal distributions. Different parameter settings were given to investigate the performances of the methods. Dose 4 was always set to be the most effective dose among the four

doses compared. We consider the following total sample sizes: 100, 150, and 200. The proportion of interim sample size was set to be 20%, resulting in interim sample sizes of 20, 30, and 40, respectively. For each case, 5000 repetitions were implemented. We summarized the simulation results as the frequency of being selected as the most effective dose in [Tables 1–3](#), according to difference sample sizes.

Table 1 Results of the example

		Placebo	Dose 1	Dose 2	Dose 3
Endpoint 1	Sample mean	3.37	3.42	3.07	2.56
	Sample std	1.61	2.1	1.62	1.53
	Probability of being the best		0	0.011	0.989
Endpoint 2	Sample mean	6.74	6.17	5.94	5.93
	Sample std	1.74	1.76	1.89	1.87
	Probability of being the best		0.07	0.45	0.479
Overall probability of being the best			0	0.005	0.474

std = standard deviation

C4: Probability of being the best dose

std = standard deviation

From the simulation results, we observed that the last method “probability of being the best dose” performed better in all cases than other methods, with higher probability of choosing the right best dose and lower probability of choosing the wrong dose.

Co-primary Endpoints

Assume the mean effects of the co-primary endpoints of four doses (dose 1 as the placebo) are to be compared, and all effects follow normal distributions. Different parameter settings were given to investigate the performances of the methods. In the first scenario, dose 4 was set to be the most effective dose among the four doses compared, with both co-primary endpoints being the most effective.

In the second scenario, the first endpoint of dose 4 is most effective, whereas the second endpoint of dose 3 is most effective. We consider the following total sample sizes: 100 and 200. The proportion of interim sample size was set to be 20%, resulting in interim sample sizes of 20 and 40, respectively. For each case, 5000 repetitions were implemented. We summarized the simulation results as the frequency of being selected as the most effective dose in [Tables 4–6](#), according to difference sample sizes.

From the simulation results, we observed that the last method “probability of being the best dose” performed better in all cases than other methods, with higher probability of choosing the right best dose and lower probability of choosing the wrong dose.

CONCLUSION

In this article, we discussed the problem of dose finding in two-stage adaptive clinical trials with the aim of selecting the most effective dose for further investigation of the next stage. Four criteria for dose selection were introduced and compared through extensive simulation studies. From the simulation results, the method of probability of being the best dose performed better than all other three methods. Thus, we recommend this method in practical applications as appropriate. In addition, an example of doseresponse of compound in treating postmenopausal women and

adjuvant breast cancer patients with vasomotor symptoms was given to illustrate the use of this method.

Semi-Parametric Time-Varying Regression Models

Thomas H. Scheike

Department of Biostatistics, University of Copenhagen, Copenhagen, Denmark

Abstract

This entry reviews statistical models that are designed for estimating such time-varying effects and testing various hypotheses about them.

Keywords: Aalen model; Additive intensity model; Cox-Aalen model; Extended Cox model; Non-proportional hazards model; Semi-parametric modeling; Survival data; Time-varying effects.

INTRODUCTION

In biomedical applications, there will often be important time-varying effects. A typical example is a treatment effect that varies over time, and two important examples are where (i) treatment efficacy fades away over time owing to, for example, tolerance developed by the patient, or in the case of infectious diseases owing to resistance developed by the targeted bacteria and (ii) a treatment with many side effects will lead to an initial adverse effect that is compensated by a beneficial effect for those surviving the initial phase.

This entry considers statistical models that are aimed at estimating such time-varying effects and testing various hypotheses about them.^[1]

The class of models depends, of course, on the response considered, and this entry considers time to event data (survival analysis), although there also exist a similar development in the context of longitudinal data. For both classes of data, the aim is to estimate the effect of a possibly time-varying treatment effect while correcting for other covariates.

FLEXIBLE MODELING OF SURVIVAL DATA

In the survival context, we shall look at models where given a p dimensional covariate $X(t)$ that may vary over time (including treatment status) and an at risk indicator $Y(t)$ the intensity is

$$\lambda(t, X) = Y(t)h(X(t))\alpha(t) \quad (1)$$

where $h(t) = t$ or $h(t) = \exp(t)$. Here, $\alpha(t)$ gives the time-varying effects of the covariates on as excess risk when $h(t) = t$ or as time-varying multiplicative effect when $h(t) = \exp(t)$. We will illustrate the use of these models below.

Many traditional statistical models do not have the needed flexibility to estimate and make hypothesis testing about time-varying effects. In the survival analysis context, the standard regression model is Cox's regression model^[2] where effects are assumed to lead to constant relative risk, something that is violated for many biomedical studies. Even when a treatment effect does not lead to constant relative risk, the Cox model may still provide an interesting summary statistic. However, to provide a more detailed understanding of what is going on and the summary statistic provided by the Cox model, this entry aims to present a more detailed analysis.

There have been some attempts to extend the Cox model in order to deal with time-varying effects leading to Eq. (1) when $h(t) = \exp(t)$ as described, for example.^[3–6] There is still, however, some way to a fully satisfactory apparatus to deal with time-varying effects owing to the need for a smoothing parameter. Also, some covariates will have effects that are not well described as being multiplicative.

One important alternative to the proportional hazards model is Aalen's additive hazard model ($h(t) = t$).^[7–9] Aalen's additive hazard regression model is completely non-parametric and includes covariates additively in the model thus leading to an excess risk interpretation. The Aalen model is very flexible and will estimate all the covariate effects as time-varying effects.

The flexible models given by Eq. (1) will estimate the treatment effect and other prognostic factors as time varying. This is often to "big" a model that does not provide the simplest possible summary of the data. A model that only uses the flexibility where it is needed is the semi-parametric model

$$\lambda(t) = Y(t)(X^T(t)\beta(t) + Z^T(t)\gamma) \quad (2)$$

where $\beta(t)$ is a q_1 -dimensional time-varying regression coefficient, γ is a q_2 -dimensional regression coefficient,

and $(X(t), Z(t))$ is a set of $p = q_1 + q_2$ -dimensional covariate vector that is observable at time t . For this model, some effects are time-varying and other covariates lead to constant effects. In this model, important hypotheses are whether or not an effect is significantly time varying or if an effect is significant at all.

The semi-parametric version of the model additive risk model Eq. (2) was suggested by Refs. [10,11] for extensions and a procedure for hypothesis testing in the model. One advantage of the additive models is that time-varying effects are easy to estimate (with explicit estimators) and that inferential procedures for making conclusions about the time-varying effects exist.

The multiplicative version of Eq. (2) was suggested in Ref. [4]. In this model, it is also possible to test for time-varying effects,^[6] but one practical problem is that one needs to choose smoothing parameters to deal with the time-varying effects.

The additive and multiplicative models postulate different relationships between the hazard and covariates, and it is seldom clear which of the models should be preferred. The models may often be used to complement each other and to provide different summary measures. Sometimes, however, covariate effects are best modeled as multiplicative and other covariate effects are best modeled as being additive, and then one must combine the additive and multiplicative models. One useful model for combining additive and multiplicative effects is the Cox-Aalen model where

$$\lambda(t) = Y(t)(X^T(t)\beta(t)\exp(Z^T(t)\gamma)) \quad (3)$$

where some effects lead to multiplicative effects and other covariates lead to time-varying additive effects; this model is easy to fit just like the semi-parametric version of the additive risk model.^[12–13]

APPLICATIONS

Prognostic Effects for Acute Myocardial Infarction Data

Thetrandolapril cardiac evaluation trial (TRACE) study group^[14] has recorded information on 6,633 consecutive patients with myocardial infarction with the aim of studying the prognostic importance of various risk factors on mortality. We here consider a random sample of 2,000 of these patients. At the time of entry, the patients had various risk factors recorded such as age (median = 69 year and range = 23–99 year), gender [male = 1 (67%) and female = 0], congestive heart failure (CHF) [present = 1 (54%) and not present = 0], and ventricular fibrillation (VF) [present = 1 (7%) and not present = 0]. Some risk factors were expected to have strongly time-varying effects, in particular VF. The timescale used in our analysis is time since myocardial infarction. The total number of deaths in a three-year period

after entering the study was 2,351, and of these, 840 took place within the first month. Most of the cases within the first month resulted from conditions related to the presence of VF.

To illustrate the semi-parametric modeling approach, we start by fitting an additive risk model with the covariates age, gender, CHF, and VF. This leads to the following cumulative effects with 95% confidence bands (Hall-Wellner bands) (Fig. 1).

The cumulative coefficients clearly indicate that the excess risk is varying with time (the slope of the cumulatives). Formal testing for time-varying effects leads to p -values at 0.01 for age, 0.35 for sex, $p < 0.00001$ for CHF, and $p < 0.00001$ for VF. The VF and CHF conditions are strongly time varying. Age was borderline time varying, and comparing the cumulative to the cumulative in the end point divided with time (a simple estimate of its constant effect) leads to the following test process that is compared to resampled processes under the null in Fig. 2. A similar plot was produced for gender.

The plot reveals that although VF and CHF account for a great deal of time-varying effects, there is a slight effect left on age. Overall, a reasonable summary is to allow age and sex to have constant effects. Note that although age deviates considerably from the null performance in the initial phase, it has only quite minor effects even on the age scale. The plot indicates that the effect of age is slightly higher initially compared to later on.

Now, fitting a semi-parametric risk model with age and sex leading to constant excess risk (SD) yields 0.005 (0.00036) for age and 0.013 (0.009) for sex. Thus males have slightly higher risk than females, although a non-significant difference, and with a 10-year age difference resulting in an excess risk at 0.05.

By considering various additional goodness-of-fit statistics, we can see that the model provides a quite reasonable fit.

It might be preferable, however, to consider a slightly different model where age and sex lead to multiplicative effects, thus resulting in a modification of the excess risk for VF and CHF depending on age and gender. We therefore subtract the mean from age and fitted the Cox-Aalen survival model with VF and CHF as flexible additive effects and with age and gender as multiplicative effects. This leads to the additive effects depicted in Fig. 3. These are quite similar to the similar additive effects of the semi-parametric risk model, although CHF appears to lead to somewhat lower excess risk in the Cox-Aalen model.

The relative risk of were age 0.058 (0.004) and gender 0.141 (0.071), age leading to increased risk of VF and CHF and gender being borderline significant with males having increased risk. We have shown how flexible models can be applied and will give information additional to that of a standard survival model. The considered models are quite flexible, and one can obtain different summary measures from different models. Sometimes one needs to combine additive and multiplicative effects.

Treatment Effect for CSL1 Study

In this section, we applied the semi-parametric model to data from the CSL1 study conducted by the Copenhagen Study Group for Liver Diseases (CSL).^[15] This was

a randomized clinical trial where the patients were given either prednisone or placebo. During the period from 1962 to 1969, 532 patients with histologically verified liver cirrhosis were included in the trial. The data is described in detail further in Ref. [16]. In 488 patients, the initial biopsy

Fig. 2 Test processes for test of time-constant effects (thick line) and 50 random processes under the null of constant effects

Fig. 3 Cumulative excess risk estimates with 95 % pointwise confidence intervals for Cox-Aalen model for TRACE data

could later be reevaluated, and we considered only data for these patients. The patients were followed up from the date of entry into the trial to death or the closing date of the study, September 1, 1974. A number of clinical and biochemical variables were registered during the study period. We considered only gender (males = 1/females = 0), age, and the treatment (prednisone = 1).

We started by considering the flexible multiplicative extension of the Cox regression model. This led to cumulative effects estimated using bandwidth equal to three years and local linear fitting to avoid edge effects. These are shown in Fig. 4.

Tests for time-varying effects indicated that all variables were well described as being constant. Prior to the study, it was suspected that the treatment effect might wear off during the study. After successive testing of time-varying effects, we therefore considered a model where age and gender had constant effect. These constant effects were age 0.032 (0.003) and gender 0.330 (0.059). This led to a time-varying effect of treatment similar to the one depicted in Fig. 4 that shows a treatment effect that has some initial effect that wears off. The estimate in this model depends on the smoothing parameter, and we provide below an alternative description of the

Fig. 4 Cumulative relative risk estimates for Cox regression model with time-varying effects for CSL data

Fig. 5 Cumulative excess risk estimates for treatment with 95% pointwise confidence intervals based on Cox-Aalen model for CSL data

treatment effect using the Cox-Aalen model. A reasonable summary appears to be given by the standard Cox regression, and this leads to effects for age and gender, which are similar to those given just above, and a relative risk treatment effect at -0.045 (0.057)—in conclusion, a weakly non-significant protective effect.

Alternatively one may summarize the treatment effect by computing its excess risk in an additive model that is equal to -0.039 (0.051). Excess risk can be translated into increased survival as a function of time by $\exp(-0.039 \times t)$, thus implying, for example, that the five-year survival is 18 % better for subjects getting prednisone.

Finally, we take a look at the estimate of the time-varying effect of prednisone using the Cox-Aalen survival model where gender and sex have multiplicative effects. Fig. 5 shows the effect of prednisone on the excess risk scale. This gives pretty much the same overall impression as the estimate on the relative risk scale. One advantage, however, is that this estimate is independent of any smoothing parameter.

If we consider the time-interval from one to three years, only the treatment effect becomes borderline significant.

SOFTWARE

Software to fit the models using R (Splus) is available in form of the R-package *timereg* that can be downloaded from <http://cran.r-project.org/web/packages/timereg/>.

CONCLUSIONS

This entry demonstrated that there do exist models for studying more closely time dynamics of covariate effects. In the context of survival data, these flexible models can provide a more detailed and more biologically sensible

description of the underlying data. This is of practical relevance in many biopharmaceutical studies where treatment effects are expected to be time varying. We have considered three different model classes here for obtaining a description of the time dynamics: extended Cox models, additive risk models, and the Cox-Aalen model, which is a flexible combination of the Cox and additive Aalen model.

Sequential Estimation: Additive Hazards Rate Model with Staggered Entry

Laurent Bordes

*Laboratoire de Mathématiques Appliquées, Université de Pau et des Pays de l'Adour,
Pau, France*

Christelle Breuils

Département STID, IUT de Metz, Metz, France

Abstract

This entry proposes estimators of the additive hazards rate model in the presence of right-censoring and staggered entries and also touches on the problems of sequential estimations.

Keywords: Additive hazards model; Continuous-time martingales; Empirical processes; Sequential estimation Staggered entry; Survival analysis.

INTRODUCTION

In semiparametric survival studies that include covariates, it is often assumed that covariates have a multiplicative effect on the hazard rate function leading to the famous Cox Proportional Hazard Model (PHM). However, several studies have proved that the hazard proportionality can fail, and thus, alternative models are necessary. The Additive Hazards Model (AHM), like the PHM, allows easy interpretation of covariate effects. It assumes that conditionally, on its covariate, an individual has a hazard function equal to an unknown baseline hazard rate function plus a function of a covariate, which depends on an unknown regression parameter, similarly for the PHM. Another interest of the AHM is that there exist explicit estimators for the unknown parameter of the model, which is no longer true for the PHM, and more generally, for almost all semiparametric lifetime regression models.

In this entry, we propose estimators of the AHM in the presence of right-censoring and staggered entries. That is, we observe lifetimes of two types. Either it can be the duration of interest or it can be a censoring time, in which case we only know that the duration of interest is larger than the duration observed. This is the right-censoring mechanism. Moreover, we want to note that individuals are recruited at different times (staggered entry). Therefore, at the time of study, the duration of interest can be censored by the time lapsed entry time and the calendar time.

Parameter estimation accounting staggered entry is often referred as sequential analysis in the survival analysis literature. In the last decade, attention has been paid to derive specific methods to evaluate large sample properties of sequential estimators. These works always assume that,

for a fixed study interval, the number of observations can be arbitrarily large. In this entry, we show that if we assume that the entry process is a Poisson process with parameter growing to infinity, then the large sample assumption is equivalent to a large value for the parameter of the entry process and that the asymptotic behavior of the regression parameter is unchanged, even if the estimator is indexed by a random sample size.

Finally, we discuss the problem of sequential estimations, that is, to define an earlier end to the study (stopping time) without deteriorating the quality of estimators (e.g., confidence regions with fixed width).

PARAMETERS ESTIMATION

Regression Models

The problem is knowing when to stop the study with a prior fixed precision. This implies that the model is known and that the sample is not determined by a clinical plan or a quantity of observed events. (These techniques do not find applications in comparative clinical trials.) Thus, data are collected to estimate the regression parameter of the model (in order to determinate the influence of the covariates in the lifetime variable). This is the case when we aim to estimate a parameter for a well-known model. It is worth noticing that the end of the study is fully determined by the sequential procedure and we have no a priori techniques for it, contrary to common planned clinical trials.

Because patients are recruited in clinical trials at different times with respect to the calendar time (staggered entry), and because the time of interest is the time in trial,

it may be important to perform analysis of some characteristics of the trial time monitored by the calendar time. Such sequential analysis could allow the clinical trials to stop at the earliest time where information seems definitively sufficient to give clinical conclusions. In the presence of covariates, such analysis can be done by using PHM (see Sellke and Siegmund,^[1] Biliias et al.^[2]). In the same spirit, Tsiatis^[3] considered a large class of time-sequential tests for two sample survival data (for large sample properties see Slud^[4] and Gu and Lai^[5]). As we said in the introduction, the PHM is the most commonly used model to account covariates effects on lifetime distributions. It assumes that a duration T_i observed with a covariate Z , admits conditionally on Z at time t , a hazard rate function $\lambda(t; Z)$ defined by:

$$\lambda(t; Z) = \lambda_0(t) \exp(\beta_0^T Z(t)), \quad \forall t \in R^+,$$

where $\lambda_0(t)$ is an unknown baseline hazard rate function and β_0 an unknown regression parameter in R^p where p is the number of covariates, that is the size of Z (which can depend on time). In presence of right censoring Cox^[6] proposed an estimator of the regression parameter β_0 based on partial likelihood. One of the main advantages of PHM is that simple information on the sign of β_0 allows easy interpretation of covariate effects. However, as noted by Huffer and McKeague,^[7] the proportionality assumption on hazards can failed and then it is necessary to propose alternative models. An alternative for the PHM is the AHM proposed by Cox and Oakes^[8] which assumes that:

$$\lambda(t; Z) = \lambda_0(t) + \beta_0^T Z(t), \quad \forall t \in R^+$$

where again $\lambda_0(t)$ and β_0 are, respectively, an unknown baseline hazard rate function and an unknown regression parameter. In this model, the covariates effect is additive (again the value of β_0 allows an easy interpretation of covariates effect). Another basic lifetime regression model is the Accelerated Life Model (ALM) generalized by Lin and Ying^[9] to time-dependent covariates. It assumes that the cumulative hazard rate function $\Lambda(t; Z)$, conditionally to a covariate Z , is defined by:

$$\Lambda(t; Z) = \int_0^t \lambda(s; Z) ds = \int_0^t \exp(\beta_0^T Z(s)) \lambda_0(s) ds, \quad \forall t \in R^+,$$

where $\lambda_0(t)$ and β_0 are still unknown baseline hazard rate function and regression parameter, respectively. In this model, the covariate effects are accounted by modifying the time scale factor. There are numbers of generalizations of these basic models, see, for example Bagdonavicius, and Nikulin,^[10] Lin and Ying^[21] and Lin et al.^[22], but most of these generalizations do not allow easy interpretations of covariate effects. In the sequel we will focus our interest on the AHM for which generalizations were also proposed in Bordes.^[11]

Data Description

Suppose that we observe a n -sample $(\tau_i, X_i, \delta_i, Z_i)_{1 \leq i \leq n}$, where i denotes the i th individual, τ_i is an entry time of individual i (the time at which the individual is recruited in the study, the time at which the treatment begins, etc.), X_i denotes the minimum between the duration of interest T_i (time elapsed between the entry date and the date of the event of interest) and a censoring time C_i (time elapsed between the entry date and the date of another event than the event of interest), δ_i is a binary variable equal to 1 if X_i is equal to the time of interest T_i and 0 otherwise, and Z_i is a vector of covariates that may be time-varying; if so, $Z_i = \{Z_i(s); 0 \leq s \leq X_i\}$. With such observations, two time scales have to be considered: the calendar time (t) and the duration on study (s). A typical way to represent staggered entry is to use a Lexis diagram as it is shown on Fig. 1 above.

However, when the time elapsed from the beginning of study is t , the information available for the i -th individual is:

$$\begin{cases} X_i(t) = \min(X_i, (t - \tau_i)^+) \\ \delta_i(t) = I(T_i = X_i(t)), \end{cases}$$

where $a^+ = \max(a, 0)$, $I(A) = 1$, if A is true and 0 otherwise. It follows that the duration of interest T_i may be censored either by C_i or by $(t - \tau_i)^+$ which is the duration between the date of entry and the date at which the study is done.

Estimators for the AHM

In this section we assume that for each individual, the hazard rate function of the i th individual can be written:

$$\lambda_i(t) = \lambda(t; Z_i) = \lambda_0(t) + \beta_0^T Z_i(t),$$

where λ_0 is an unknown baseline hazard rate function and β_0 is an unknown regression parameter. Quantities to be estimated are, β_0 (in order to evaluate the covariates effects) and e.g. $\Lambda(t; Z)$ the cumulative hazard function conditionally to the covariate Z and $S(t; Z)$ the survival function conditionally to a covariate Z . Following the methodology of Lin and Ying,^[12] we propose to estimate β_0 at calendar time t and after a duration of study of s by:

$$\hat{\beta}_n(t, s) = \left(\sum_{i=1}^n \int_0^{\min(s, X_i(t))} (Z_i(u) - \bar{Z}(t, u))^{\otimes 2} du \right)^{-1} \left(\sum_{i=1}^n (Z_i(X_i(t)) - \bar{Z}(t, X_i(t))) N_i(t, s) \right),$$

where if a is a column vector $a^{\otimes 2} = a^T a$, $N_i(t, s) = I(X_i(t) \leq s; \delta_i(t) = 1)$ and

Fig. 1 Lexis diagram

$$\bar{Z}(t, s) = \frac{\sum_{i=1}^n \gamma_i(t, s) Z_i(s)}{\bar{Y}(t, s)} \quad \text{and} \\ \bar{Y}(t, s) = \sum_{i=1}^n \gamma_i(t, s).$$

If the origin of the calendar time is defined at the beginning of the study, at calendar time t , β_0 is estimated by $\hat{\beta}_n(t, t)$. In this case, for $s \in [0, t]$ the estimator of $\Lambda(s; Z)$ is defined by:

$$\hat{\Lambda}_n(t, s; Z) = \sum_{i=1}^n \frac{N_i(t, s)}{\bar{Y}(t, X_i(t))} - \hat{\beta}_n(t, t) \\ \times \int_0^s (\bar{Z}(t, u) - Z(u)) du.$$

Therefore, the estimator of the survival function $S(t; Z)$ is given for $s \in [0, t]$ by:

$$\hat{S}_n(t, s; Z) = \exp \left(\hat{\beta}_n^T(t, t) \int_0^s (\bar{Z}(t, u) - Z(u)) du \right) \\ \times \prod_{\substack{1 \leq i \leq n; \\ N_i(t, s) = 1}} \left(\frac{\bar{Y}(t, X_i(t)) - 1}{\bar{Y}(t, X_i(t))} \right).$$

Large Sample Properties

Several authors show that standard counting process theory (see Andersen et al.^[13] or Fleming and Harrington^[20]) cannot be applied to obtain large sample properties of the above estimators with respect to the two time scales (see, e.g., Sellke and Siegmund^[1]). Biliás et al.^[2] developed a general empirical process approach (see Pollard^[14]) that allows deriving large sample properties for the PHM

estimators with staggered entry. This approach had been applied to the AHM by Bordes^[15] proving that under standard regularity assumptions, quantities:

$$\sqrt{n}(\hat{\beta}_n(t, s) - \beta_0), \\ \sqrt{n}(\hat{\Lambda}_n(t, s; Z) - \Lambda(s; Z))$$

and

$$\sqrt{n}(\hat{S}_n(t, s; Z) - S(s; Z))$$

converge weakly to Gaussian random field indexed by $(t, s) \in D = \{(u, v) \in \mathbb{R}^+; t_* \leq v \leq u \leq t^*\}$ where t_* and t^* are, respectively, the time at which starts the study (not recruitments) and the maximum duration of the study. Let us now give estimators of asymptotic variances of each of the previous estimators. We have:

$$\text{Var}(\hat{\beta}_n(t, s)) \approx \hat{A}^{-1}(t, s) \times \hat{B}(t, s) \times \hat{A}^{-1}(t, s),$$

where

$$\hat{A}(t, s) = \left(\sum_{i=1}^n \int_0^{\min(s, X_i(t))} (Z_i(u) - \bar{Z}(t, u))^{\otimes 2} du \right),$$

and

$$\hat{B}(t, s) = \sum_{i=1}^n (Z_i(X_i(t)) - \bar{Z}(t, X_i(t)))^{\otimes 2} N_i(t, s).$$

$$\text{Var}(\hat{\Lambda}_n(t, s; Z)) \approx \sum_{i=1}^n \frac{N_i(t, s)}{\bar{Y}^2(t, X_i(t))} \\ + 2 \left\{ \sum_{i=1}^n \frac{(Z_i(X_i(t)) - \bar{Z}(t, X_i(t)))^T}{\bar{Y}(t, X_i(t))} N_i(t, s) \right\} \\ \times \hat{A}^{-1}(t, s) \hat{\mu}(t, s) + \hat{\mu}^T(t, s) \hat{A}^{-1}(t, s) \\ \times \hat{B}(t, s) \times \hat{A}^{-1}(t, s) \hat{\mu}(t, s).$$

and

$$\text{Var}(\hat{S}_n(t, s; Z)) \approx \hat{S}_n^2(t, s; Z) \text{Var}(\hat{\Lambda}_n(t, s; Z)).$$

SEQUENTIAL STOPPING RULES

Because the human or financial cost of a survival study can increase with the time, it is necessary to find procedures that allow having an early stop of the experiments. Thus, if we stop the study when a required precision level on estimation is reached, we have to define the so called stopping rules (see Ghosh et al.^[16]). All this stopping rules lead to obtain the best compromise between an accurate estimation and a early end of the study. Thus, the goal of the sequential stopping rule is to provide the required sample size N_α for which a fixed level of precision $\alpha > 0$

is obtained. Sequential estimation based on fixed width confidence region as defined e.g., by Dmitrienko and Govindarajulu^[17] are the most commonly used stopping rules. As a consequence of these methods, the sample size is generally random, and it increases with the precision level.

With such a stochastic sample size, large sample properties of the regression estimator need to be extended. In order to obtain these properties, we need to assume regular properties for the stopping variable, that is, we suppose the existence of a deterministic sequence $(n_\alpha)_{\alpha \rightarrow 0}$ such that we have:

$$N_\alpha/n_\alpha \xrightarrow{p} 1 \quad \text{and} \quad n_\alpha \rightarrow +\infty \text{ as } \alpha \rightarrow 0,$$

where N_α is the sample size for a level of precision α . Notice that here the maximum precision is therefore $\alpha=0$. A sequence of random sample size $(N_\alpha)_{\alpha \rightarrow 0}$ that satisfies the above convergence is said to be regular.

Using the above explicit formulation for the estimator of β_0 of the AHM, we need to obtain asymptotics for

$$\sqrt{N_\alpha}(\hat{\beta}_{N_\alpha}(t, t) - \beta_0).$$

The theory developed in Bordes and Breuils^[18, 19] allows us to prove that, under suitable regularity conditions given in Bordes,^[15] for a fixed time of study t , the estimator indexed by either a deterministic sample size n (with $n \rightarrow +\infty$) or by a regular random sample size N_α (with $\alpha \searrow 0$), has the same asymptotic behavior. It follows that the estimator of the variance of $\hat{\beta}_{N_\alpha}(t, t)$ is the same as the estimator of the variance of $\hat{\beta}_n(t, t)$ simply replacing n by N_α in the expression of $\text{Var}(\hat{\beta}_n(t, s))$

Example 1. Considering the case of 1-D covariates, we know from the previous paragraph that $\sqrt{n}(\hat{\beta}_n(t, s) - \beta_0)$ is approximately Gaussian with asymptotic variance estimated by $\hat{\sigma}_n^2(t, s)$. If $u_{\theta/2}$ satisfies, $2\Phi(u_{\theta/2}) - 1 = 1 - \theta$ where Φ is the cumulative distribution function of standard Gaussian distribution, then

$$\hat{I}_\theta = \left[\hat{\beta}_n(t, s) - \frac{u_{\theta/2} \hat{\sigma}_n(t, s)}{\sqrt{n}}, \hat{\beta}_n(t, s) + \frac{u_{\theta/2} \hat{\sigma}_n(t, s)}{\sqrt{n}} \right]$$

is approximately a $(1-\theta)$ -confidence interval for the unknown parameter β_0 . If we want a precision of estimation specified by length $(\hat{I}_\theta) \leq 2\alpha$ then n have to satisfy the inequality:

$$n \geq \frac{u_{\theta/2}^2 \hat{\sigma}_n^2(t, s)}{\alpha^2}.$$

Therefore, we decide to stop the study when the above inequality is satisfied and for $n \geq n_0$, where n_0 is the minimum size of the sample that ensures that we are not too far

from large sample properties. With such a stopping rule, the sample size at time t is random and equal to:

$$N_\alpha(t) = \inf \left\{ n \geq n_0; n \geq \frac{u_{\theta/2}^2 \hat{\sigma}_n^2(t, s)}{\alpha^2} \right\}.$$

Finally, by the preliminary considerations of this section, we obtain that for a small value of α and a large value of n , $\sqrt{N_\alpha(t)}(\hat{\beta}_{N_\alpha(t)}(t, s) - \beta_0)$ and $\sqrt{n}(\hat{\beta}_n(t, s) - \beta_0)$ have approximately the same Gaussian distribution.

Example 2. Here is a very simple example where we consider that entry dates follow a Poisson process with parameter $1/\alpha$. If we want to traduce the fact that on a given time interval $[0, t]$, the number of observations grows, we may consider that $\alpha \rightarrow 0$. Therefore, by classical results on Poisson processes, we have:

$$\frac{N_\alpha(t)}{t/\alpha} \xrightarrow{p} 1, \quad \text{as } \alpha \rightarrow 0$$

where

$$N_\alpha(t) = \sum_{i \geq 1} 1(\tau_i \leq t).$$

Thus, by preliminary results of this section, we know that for a fixed time t , the asymptotic Gaussian distribution of $\sqrt{N_\alpha(t)}(\hat{\beta}_{N_\alpha(t)}(t, t) - \beta_0)$ for α small enough, is the same as the asymptotic Gaussian distribution of $\sqrt{n}(\hat{\beta}_n(t, t) - \beta_0)$ for a large value of n .

CONCLUSION

In this paper we discussed inference procedures for the AHM with staggered entry. We showed that estimators are naturally indexed by two time scales: the calendar time and the duration of study. We proposed estimators of the unknown parameters of the AHM that account these two time scales and gave explicit formulae for their asymptotic variances. In “Sequential Stopping Rules” we discussed sequential methods of estimation of the regression parameter when an early stop of the study is necessary. We showed that such sequential methods lead to estimators indexed by random sample size and that whenever the random sample size is regular, the nonsequential and the sequential estimators have the same large sample properties.

The above staggered entry model assumes that at a fixed time of study s , the number of individuals is a deterministic value n . Moreover, it is supposed that the number of individuals that “fall” in the study interval $[0, s]$ increases and tends to infinity (this is the sense of the “large sample” theory developed e.g. in Biliás et al.^[21]). Because the entry times are random, it is more reasonable to consider that the number of individuals that are present in the study at fixed time of study is a random variable and to consider

time asymptotic for the estimators. In this case the random sample size would be

$$N_t = \sum_{i \geq 1} 1(\tau_i \leq t).$$

Therefore, estimators of the unknown parameters of the AHM model will be indexed by time t . In a further work we will discuss the asymptotic behavior of estimators when $t \rightarrow +\infty$. As in Example 1 of “Sequential Stopping Rules,” we can construct time stopping rule T_α but asymptotic behavior of estimators indexed by such random time are unknown and need further investigations.

Abstract

Spontaneous reporting systems containing reports of adverse health outcomes associated with the use of pharmaceutical products represent a valuable source of information for drug safety evaluation. This article provides an overview of statistical methods used in determining whether elevated frequencies in the reporting of adverse events provide evidence of potential safety signals in passive pharmacovigilance. Both frequentist and Bayesian methods are used to examine disproportionality in the reporting rates of adverse events associated with the drug of interest relative to that for a reference drug or group of drugs. Statistical issues in the application of disproportionality methods are discussed, including the selection of a threshold level for signal identification and characterization of false discovery rates. Other issues relevant to the analysis and interpretation of adverse event data are also noted, including under-reporting and confounding. This discussion provides a guide for practitioners in the selection of appropriate statistical methods for signal detection in passive pharmacovigilance and in the interpretation of the analytic results.

Keywords: Adverse Drug Reactions; Adverse Events; Bayesian Approaches; Disproportionality Methods; False Discovery Rate; Frequentist Approaches; Passive Surveillance; Signal Threshold Level; Simultaneous Hypothesis Testing; Spontaneous Reporting Data.

1 INTRODUCTION

Prescription medications undergo rigorous preclinical and clinical testing before receiving market authorization by regulatory authorities (Institute of Medicine^[1,2]). Despite extensive premarket testing under controlled conditions, it is not possible to evaluate all possible adverse effects that might be associated with the use of a particular medication in diverse patient populations. Consequently, pharmaceutical products are subject to post-market evaluation following their introduction into the marketplace using statistical methods for pharmacovigilance (Huang, Guo et al.,^[3] Candore, Juhlin et al.^[4]).

Pharmacovigilance seeks to identify safety signals heralding potential risks of adverse drug reactions (ADRs) under real world conditions of use. The World Health

Organization (WHO) defines pharmacovigilance as “the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other drug-related problems” (WHO^[5]). Reports of adverse drug reactions (ADRs) are compiled in databases such as Canada Vigilance maintained by Health Canada, the FDA Adverse Events Reporting System (FAERS) maintained by the US Food & Drug Administration (FDA), and the EudraVigilance maintained by the European Medicines Agency (EMA). The WHO consolidates reports from multiple jurisdictions internationally within the WHO Vigibase, which contains more than 12 million individual case safety reports (ICSRs) as of December 2015. Recent analyses of the Vigibase data have suggested possible associations between botulinum neurotoxin type A (BoNT-A) used as an anti-spastic agent in children with cerebral palsy

and mortality (Montrastruc, Marque et al.^[6]), and between the use of quinolones and suicidal behaviors (Samyde, Petit et al.^[7]).

Historically, passive pharmacovigilance has focused on the analysis of data from spontaneous reporting (SR) systems, such as the ICSRs in Vigibase (Shankar^[8]). Spontaneous reporting data typically includes limited patient information within the ICSR, often limited to age and sex. Further, due to the self-reporting nature of passive pharmacovigilance systems, SR data has been used primarily to motivate the formulation of drug safety hypotheses. More recently, increasing emphasis has been placed on active pharmacovigilance, using longitudinal observational datasets (LODs) to investigate the risk of adverse drug reactions within large patient populations with more detailed patient information, including co-morbidity and polypharmacy (Huang, Moon et al.,^[9] Zhuo, Farrell et al.^[10]). Within the last decade, major initiatives such as the establishment of the Canadian Network for Observational Drug Effect Studies (CNODES) in Canada (Suisse, Henry et al.^[11]) and the Sentinel Initiative in the United States (Ball, Robb et al.^[12]) have begun to harness the increasing availability of LODs for drug safety and effectiveness evaluation. Initiatives such as these are beginning to yield results that will serve to establish proof-of-principle of LODs as a key resource for drug safety evaluation. As an example, in a combined analysis of data from six participating sites in Canada, the United States, and the United Kingdom involving over 1.5 million patients, Azoulay, Fillion et al.^[13] reported no association between incretin-based drugs acute pancreatitis, in comparison with other oral antidiabetic drugs.

While active pharmacovigilance will play an increasing important role in drug safety evaluation in the future, passive pharmacovigilance remains an important tool for the early detection of safety signals (Chakravarty, Izem et al.^[14]). The signals identified using SR data can be investigated in more depth using LODs.

This article focuses on statistical methods for the early detection of adverse events (AEs) based on SR data (Candore, Juhlin et al.^[4]). Specifically, we provide a review of the signal detection methods that have been proposed to date, including frequentist and Bayesian approaches. These methods look to identify ‘signals of disproportionate reporting’ (SDRs) in spontaneous reporting data. They evaluate evidence in support of increased reporting rates rather than potential causal relationships (Hauben and Aronson^[15]). The statistical basis for each of the methods considered is presented, along with important issues in their application, such as under-reporting, and the control of false positive rates within a multiple testing context. This review will help practitioners working in the field of pharmacovigilance identify the most appropriate statistical methods to assist them in identifying safety signals in SR data that warrant intervention or further investigation.

In order to facilitate and motivate the presentation to follow, the [Section 2](#) describes the nature of spontaneous

reporting data, and provides an introduction to the passive pharmacovigilance methods for adverse event detection, along with a discussion of the challenges faced when analyzing SR data. [Section 3](#) presents the frequentist methods for signal detection, while [Section 4](#) describes the Bayesian approaches. [Section 5](#) discusses two important issues that arise in the analysis of SR data: decision criteria for signal detection, and adjustments for multiple testing. A conclusion and discussion is given in [Section 6](#), where we elaborate further on additional issues encountered in the application of disproportionality methods in passive pharmacovigilance.

2 PASSIVE PHARMACOVIGILANCE

Spontaneous reporting data can be conveniently summarized in the form of contingency tables as shown in [Table 1](#). Imagine that a particular data set includes information on I drugs and J AEs. We let D_i represent the i -th drug, and A_j the j -th adverse event. The entry n_{ij} in the table denotes the number of patients who were treated with drug D_i and experienced adverse event A_j .

The Observational Medical Outcomes Partnership (OMOP)^[16] aims to identify “the most reliable methods for analyzing huge volumes of data drawn from heterogeneous sources, and has compiled a methods library that includes methods for disproportionality analysis. These techniques compare the reporting rate of a particular AE for a given drug with that for all other drugs and AEs, either individually or combined. Alternatively, they compare the observed number of reports of the drug/AE combination with the expected number of reports under the assumption of no association between the drug and the AE. When the reporting rate of a particular AE for a given drug is compared with its counterpart over all other drugs and AEs combined, the analysis can be based on a collapsed 2×2 version of the above table as represented below in [Table 2](#).

The common disproportionality measures cited by OMOP include the proportional reporting ratio, PRR (Evans, Waller et al.^[17]), the reporting odds ratio, ROR (Van

Table 1 Contingency table summarizing the number of each of J adverse events to each of I different drugs

Total	$n_{\cdot j}$	$n_{\cdot j'}$	n

Puijenbroek, Bate et al.^[18] Rothman, Lanes et al.^[19], the (multi) gamma-Poisson shrinker, MGPS (DuMouchel,^[20] DuMouchel and Pregibon^[21]), and the Bayesian Confidence Propagation Neural Network, BCPNN (Bate, Lindquist et al.^[22]). These methods rely exclusively on the number of reports of adverse events, and do not consider drug exposure-time information within the patient population.

The disproportionality methods for spontaneous AE reporting can be categorized as frequentist or Bayesian. Of those above cited above, the PRR and the ROR are included in the former category. Other frequentist approaches include the chi-square test for independence, with or without continuity correction (Yates,^[23] Yule and Kendall,^[24] Greenwood and Nikulin^[25]), and the reporting Fisher's exact test (Agresti,^[26] Ahmed, Dalmasso et al.^[27]). More recently, a 'frequentist' version of the information component (IC) and a likelihood ratio test (LRT) have also been proposed (Huang, Guo et al.^[3] Huang, Zalkikar et al.^[28]). The IC measure has previously been used in the BCPNN, which, along with the MGPS, are the Bayesian disproportionality methods identified by OMOP. They fall under a subcategory known as empirical Bayes techniques.

The general principle underlying signal detection in disproportionality methods involves the comparison of a 'score' for a particular drug/AE combination with a 'threshold' level. These scores can be viewed as a numerical summary measure of the relationship between a given AE and a certain drug obtained by comparing the frequency of occurrence of the AE with the drug to the frequency of the same AE with all other drugs. A test of the null hypothesis of no association between the drug and the AE is performed. A score exceeding the threshold results in rejection of this hypothesis, and suggests an association between the drug and AE under consideration. If the hypothesis is only concerned with a single combination, the Type I error is maintained at a specified level. However, it is often the case that there are many drug/AE combinations that are simultaneously of interest: in such situations, a number of the disproportionality methods do not control the overall Type I error rate across the multiple hypothesis tests conducted, resulting in too many false positive alarms. The number of false positives in a multiple testing context can be reduced by increasing the threshold level, although this

will increase the number of false negatives. A number of solutions to this issue have been proposed, including the adaptation of the False Discovery Rate, or FDR (Benjamini and Hochberg^[29]), that was originally applied in multidimensional gene and protein microarray analysis (Efron, Tibshirani et al.^[30]).

A number of authors have estimated false positive and false negative error rates for common signal detection methods using simulated data (Rolka, Bracy et al.,^[31] Roux, Thiessard et al.,^[32] Almenoff, LaCroix et al.,^[33] Matsushita, Kuroda et al.,^[34] Ahmed, Dalmasso et al.,^[27] Ahmed, Thiessard et al.,^[35] Huang, Zalkikar et al.^[28]). In addition to identifying issues relating to the selection of threshold levels, these studies have also highlighted challenges in comparing the performance of Bayesian and frequentist approaches. These and other issues encountered when analyzing SR data will be discussed in [Sections 5 and 6](#). The next two sections are devoted to frequentist and Bayesian approaches for signal detection in passive pharmacovigilance.

3 FREQUENTIST METHODS

Since SR data is a collection of AE reports with information on prescription drug utilization by the individual making the report, the data are essentially retrospective: conditional on AE status, the drugs that the individual was taking in advance of making the report are observed. Spontaneous reporting data therefore needs to be analyzed as such. Consider the collapsed 2×2 contingency table given in [Table 2](#). Let π_{ij} be the probability of jointly observing the i -th drug and the j -th AE. In addition, let $\pi_{i\cdot}$ and $\pi_{\cdot j}$ be the marginal probabilities of observing the i -th drug and the j -th AE, respectively. Therefore, $\pi_{i'} = 1 - \pi_{i\cdot}$ and $\pi_{\cdot j'} = 1 - \pi_{\cdot j}$ are the marginal probabilities of not observing the i -th drug and the j -th AE, respectively. Similarly, $\pi_{ij'} = \pi_{i\cdot} - \pi_{ij}$ is the joint probability of observing the i -th drug, but not the j -th AE, while $\pi_{i'j} = \pi_{\cdot j} - \pi_{ij}$ is the joint probability of observing the j -th drug, but not the i -th AE drug. Finally, $\pi_{i'j'} = \pi_{i'} - \pi_{i'j} = \pi_{\cdot j'} - \pi_{ij'}$ is the joint probability of observing neither the i -th drug nor the j -th AE. These joint and marginal probabilities are summarized in [Table 3](#), which takes on a form identical to that summarizing SR data in [Table 2](#).

The joint and marginal probabilities given in [Table 3](#) allow for the determination of four conditional probabilities of observing (or not observing) the i -th drug conditional on reporting (or not reporting) the j -th AE. The probability of observing the i -th drug conditional on reporting the j -th AE is given by $\pi_{i|j} = \pi_{ij} / \pi_{\cdot j}$, while the probability of not observing the i -th drug conditional on reporting the j -th AE is given by $\pi_{i'|j} = \pi_{i'j} / \pi_{\cdot j}$. Given that the j -th AE was not reported, the conditional probability of observing the i -th drug is $\pi_{i|j'} = \pi_{ij'} / \pi_{\cdot j'}$, while the conditional probability of not observing the i -th drug is $\pi_{i'|j'} = \pi_{i'j'} / \pi_{\cdot j'}$. Using this

Table 3 Collapsed 2×2 contingency table summary of joint and marginal probabilities for comparing the reporting rate of the j -th adverse event for the i -th drug to that for all other drugs combined

Drug	Adverse Event		Total
	A_j	$A_{j'}$	
D_i	π_{ij}	$\pi_{ij'}$	$\pi_{i\cdot}$
$D_{i'}$	$\pi_{i'j}$	$\pi_{i'j'}$	$\pi_{i'\cdot}$
Total	$\pi_{\cdot j}$	$\pi_{\cdot j'}$	1

notation, we now summarize frequentist methods for the analysis of SR data.

Reporting Odds Ratio, ROR

For the 2×2 table given in Table 3, the ROR for the i -th drug and j -th AE is given by

$$ROR_{ij} = \frac{\pi_{i|j}/\pi_{i'|j}}{\pi_{i|j'}/\pi_{i'|j'}} = \frac{\pi_{i|j}\pi_{i'|j'}}{\pi_{i|j'}\pi_{i'|j}} = \frac{\pi_{ij}\pi_{i'j'}}{\pi_{ij'}\pi_{i'j}}$$

Notice that in the second term, the numerator $\pi_{i|j}/\pi_{i'|j}$ is simply the odds of observing the i -th drug (the ratio of the probability of observing the i -th drug to the probability of not observing it), conditional on reporting the j -th AE. The denominator $\pi_{i|j'}/\pi_{i'|j'}$ is the odds of observing the i -th drug conditional on the j -th AE not being reported. Thus, the larger the value of ROR_{ij} , the higher the association between the i -th drug and the j -th AE. In fact, if $ROR_{ij} > 1$, the odds of observing drug i given the j -th AE is reported exceed the odds if the j -th AE is not reported, while the opposite is true if $ROR_{ij} < 1$.

The reporting odds ratio ROR_{ij} is estimated by

$$\widehat{ROR}_{ij} = \frac{n_{ij}n_{i'j'}}{n_{ij'}n_{i'j}}$$

While the distribution of $\widehat{ROR}_{ij}$ can be highly skewed, particularly if n_{ij} or $n_{i'j}$ are very small, the asymptotic distribution of $\log(\widehat{ROR}_{ij})$ is normal. Note that $\log(\widehat{ROR}_{ij})$ is not defined when either $n_{ij'}$ or $n_{i'j}$ are zero. Applying the delta method, the estimated variance of $\log(\widehat{ROR}_{ij})$ is

$$\hat{V}[\log(\widehat{ROR}_{ij})] \approx \frac{1}{n_{ij}} + \frac{1}{n_{i'j}} + \frac{1}{n_{ij'}} + \frac{1}{n_{i'j'}}$$

An approximate $100(1 - \alpha)\%$ confidence interval for ROR_{ij} is therefore given by

$$\left(e^{\log(\widehat{ROR}_{ij}) - z_{\alpha/2} \sqrt{\hat{V}[\log(\widehat{ROR}_{ij})]}}, e^{\log(\widehat{ROR}_{ij}) + z_{\alpha/2} \sqrt{\hat{V}[\log(\widehat{ROR}_{ij})]}} \right)$$

where $z_{\alpha/2}$ is the $\alpha/2$ upper critical value of the standard normal distribution. If the entire interval situates entirely

above 1, the j -th AE can be interpreted as statistically significant evidence of a signal of a disproportionate reporting rate for the i -th drug at significance level α .

Proportional Reporting Ratio, PRR

The PRR for the i -th drug and j -th AE is given by

$$PRR_{ij} = \frac{\pi_{j|i}}{\pi_{j|i'}} = \frac{\pi_{ij}/\pi_{i\cdot}}{\pi_{i'j}/\pi_{i'\cdot}}$$

It can be interpreted as the ratio of the conditional probability of observing the j -th AE given that the reporter has been treated with the i -th drug to the conditional probability of observing the j -th AE given that the i -th drug was not prescribed. Thus, if $PRR_{ij} > 1$, the probability of observing the j -th AE given that the i -th drug has been prescribed exceeds the corresponding probability when the i -th drug is not used.

The proportional reporting ratio PRR_{ij} is estimated by

$$\widehat{PRR}_{ij} = \frac{n_{ij}/n_{i\cdot}}{n_{i'j}/n_{i'\cdot}}$$

Since the asymptotic distribution of $\log(\widehat{PRR}_{ij})$ is approximately normal, its variance can be estimated by

$$\hat{V}[\log(\widehat{PRR}_{ij})] \approx \frac{1}{n_{ij}} + \frac{1}{n_{i\cdot}} + \frac{1}{n_{i'j}} + \frac{1}{n_{i'\cdot}}$$

An approximate $100(1 - \alpha)\%$ confidence interval for PRR_{ij} is therefore given by

$$\left(e^{\log(\widehat{PRR}_{ij}) - z_{\alpha/2} \sqrt{\hat{V}[\log(\widehat{PRR}_{ij})]}}, e^{\log(\widehat{PRR}_{ij}) + z_{\alpha/2} \sqrt{\hat{V}[\log(\widehat{PRR}_{ij})]}} \right)$$

While evidence supporting the conclusion of a disproportionate rate for the i -th drug is demonstrated when the lower limit of this interval exceeds one, there have been suggestions to modify the threshold (Evans, Waller et al.^[16]), raising it from one to two, and requiring that all $n_{ij} \geq 3$. The implications of the choice of criteria for signal detection are discussed in detail in Section 5.

Note that with the PRR, inference is conditional on the drug, and not on the AE, which is contrary to the nature of SR data. However, consider the case of a rare AE, regardless of the drug administered. In this case, we may assume that both n_{ij} and $n_{i'j}$ are very small relative to $n_{ij'}$ and $n_{i'j'}$, respectively. Since $n_{i\cdot} = n_{ij} + n_{i'j} \approx n_{ij'}$ and $n_{i'\cdot} = n_{i'j} + n_{i'j'} \approx n_{i'j'}$, in the case of rare events, we can estimate PRR_{ij} by

$$\widehat{PRR}_{ij} = \frac{n_{ij}/n_{i\cdot}}{n_{i'j}/n_{i'\cdot}} \approx \frac{n_{ij}/n_{ij'}}{n_{i'j}/n_{i'j'}} = \frac{n_{ij}n_{i'j'}}{n_{ij'}n_{i'j}} = \widehat{ROR}_{ij}$$

Care must nevertheless be taken in using the PRR and ROR for rare AEs since, if $n_{i\cdot}$ for the i -th drug is much smaller

than n_i for all other drugs, extremely small but similar values for n_{ij} and n_j may result in a conclusion that the j -th AE can be interpreted as a signal of a disproportional reporting rate for the i -th drug that is based on negligible occurrences of the AE, both for the i -th drug, as well as all other drugs.

Frequentist-Based Information Component, IC

Huang, Guo et al.^[3] propose a frequentist version of the IC for examining the relationship between the i -th drug and j -th AE. The IC is based on the relative reporting rate, or RRR. The RRR essentially compares the probability of observing the i -th drug and j -th AE with this same probability under the assumption of independence, or no association. Since the joint probability of observing the i -th drug and j -th AE is π_{ij} , while the analogous probability under the assumption of independence of drug i and the j -th AE is $\pi_i \cdot \pi_j$. The RRR is simply the ratio of these two probabilities, given by

$$RRR_{ij} = \frac{\pi_{ij}}{\pi_i \cdot \pi_j}$$

The estimate of the RRR_{ij} is

$$\widehat{RRR}_{ij} = \frac{n_{ij}/n}{(n_i/n)(n_j/n)} = \frac{n_{ij}}{(n_i \cdot n_j)/n} = \frac{n_{ij}}{E_{ij}}$$

where

$$E_{ij} = \frac{n_i \cdot n_j}{n}$$

is the expected number of reports of the i -th drug and j -th AE combination under the assumption of independence. Clearly, values of $\widehat{RRR}_{ij}$ much in excess of one would suggest that the j -th AE could be interpreted as a signal of a disproportionate AE rate for drug i .

The IC is defined as

$$IC_{ij} = \log_2(RRR_{ij}) = \log_2\left(\frac{\pi_{ij}}{\pi_i \cdot \pi_j}\right)$$

and is estimated by

$$\widehat{IC}_{ij} = \log_2\left[\frac{n_{ij}}{(n_i \cdot n_j)/n}\right] = \log_2\left(\frac{n_{ij}}{E_{ij}}\right)$$

provided that n_i , n_j , and n_{ij} are all greater than zero. Noting that

$$\log_2\left[\frac{n_{ij}}{(n_i \cdot n_j)/n}\right] = \frac{\log\left[\frac{n_{ij}}{(n_i \cdot n_j)/n}\right]}{\log 2}$$

and that the asymptotic distribution of $\widehat{IC}_{ij}$ is approximately normal, its variance can be estimated by

$$\widehat{V}(\widehat{IC}_{ij}) \approx \frac{1}{(\log 2)^2} \left(\frac{1}{n_{ij}} + \frac{1}{n_i} + \frac{1}{n_j} \right)$$

An approximate $100(1 - \alpha)\%$ confidence interval for IC_{ij} is therefore given by

$$\left(\widehat{IC}_{ij} - z_{\alpha/2} \sqrt{\widehat{V}(\widehat{IC}_{ij})}, \widehat{IC}_{ij} + z_{\alpha/2} \sqrt{\widehat{V}(\widehat{IC}_{ij})} \right)$$

If this interval lies entirely above zero, then the j -th AE has been reported at a disproportionate rate for the i -th drug, providing evidence of a signal of an AE.

Chi-Square Test of Independence

The chi-square (χ^2) test of independence formalizes the joint probability comparison of the RRR. However, the test requires that the SR data are obtained via multinomial sampling. Note that when conditioning on the j -th AE, the column totals, n_j , are fixed. This is the case when a set of n_j records with the j -th AE are examined to determine the incidence of the i -th drug. In multinomial sampling, only the total number of records examined, n , is fixed. For such a scheme, a set of n records would be selected to determine the prevalence of both the i -th drug and the j -th AE. Returning for the moment to the case of conditioning on the j -th AE, there is an analogous chi-square test for such data, called the chi-square test for homogeneity. In the chi-square test for homogeneity, the n_{ij} observed in the 2×2 table are compared to their expected values under the assumption that $\pi_{i|j} = \pi_{i|j'}$ (that is, the probability of observing the i -th drug conditional on reporting the j -th AE is the same as the analogous probability conditional on the j -th AE not being reported). In the chi-square test of independence, the n_{ij} are compared to their expected values under the assumption that $\pi_{ij} = \pi_i \cdot \pi_j$ (implying no association, or independence, between the i -th drug and the j -th AE). However, despite the fact that the derivation of the appropriate formula for investigating whether the j -th AE is a signal differs for the two chi-square tests, the resulting formula for the chi-square statistic turns out to be exactly the same for the two procedures! In what follows, we therefore describe the test for independence, bearing in mind that it is appropriate only for multinomial sampling, and not when data are collected conditional on AE status.

The chi-square test for independence requires the calculation of a test statistic that uses each cell of the 2×2 table. The test statistic is given by

$$\chi_{ij}^2 = \frac{(n_{ij} - E_{ij})^2}{E_{ij}} + \frac{(n_{ij'} - E_{ij'})^2}{E_{ij'}} + \frac{(n_{i'j} - E_{i'j})^2}{E_{i'j}} + \frac{(n_{i'j'} - E_{i'j'})^2}{E_{i'j'}}$$

Under the hypothesis of independence, this test statistic follows a chi-square distribution with 1 degree of freedom. Hence $P(\chi^2_1 > \chi^2_{ij})$ represents an approximate p-value for assessing whether the j -th AE can be interpreted as a signal of a disproportional rate for the i -th drug. Evans, Waller et al.^[17] suggest further conditions for concluding that the j -th AE is a signal, adding that it should be the case that $\chi^2_{ij} \geq 4$ and $n_{ij} \geq 3$.

It is important to note here that while the n_{ij} are counts and therefore discrete, the chi-square distribution followed by the test statistic χ^2_{ij} is continuous. A number of different continuity corrections have been applied to the test statistic to take this discrepancy into account. A common correction is the “0.5 continuity correction”, which leads to

$$\chi^2_{ij} = \frac{(n_{ij} - E_{ij})^2 - 0.5}{E_{ij}} + \frac{(n_{ij'} - E_{ij'})^2 - 0.5}{E_{ij'}} + \frac{(n_{i'j} - E_{i'j})^2 - 0.5}{E_{i'j}} + \frac{(n_{i'j'} - E_{i'j'})^2 - 0.5}{E_{i'j'}}$$

as the test statistic. Alternatively, Yates^[23] proposed a correction that yielded the test statistic

$$\chi^2_{ij} = \frac{(|n_{ij}n_{i'j'} - n_{ij'}n_{i'j}| - 0.5n^2)n}{n_i n_{i'} n_j n_{j'}}$$

while Yule and Kendall^[23] describe another measure involving a continuity correction called Yule's Q_{ij} , which is given by

$$Q_{ij} = \frac{n_{ij}n_{i'j'} - n_{ij'}n_{i'j}}{n_{ij}n_{i'j'} + n_{ij'}n_{i'j}}$$

It can be shown that $-1 \leq Q_{ij} \leq 1$, and that a value of $Q_{ij} = 0$ provides evidence of no association between drug i and the j -th AE. Since the variance of Q_{ij} can be estimated by

$$\hat{V}(Q_{ij}) = \frac{(1 - Q_{ij}^2)^2}{4} \left(\frac{1}{n_{ij}} + \frac{1}{n_{i'j}} + \frac{1}{n_{ij'}} + \frac{1}{n_{i'j'}} \right)$$

an approximate $100(1 - \alpha)\%$ confidence interval based on Q_{ij} as an estimate is given by

$$(Q_{ij} - z_{\alpha/2} \sqrt{\hat{V}(Q_{ij})}, Q_{ij} + z_{\alpha/2} \sqrt{\hat{V}(Q_{ij})})$$

The j -th AE would be considered as having been reported at a disproportionate rate for the i -th drug if the above interval lay entirely above zero.

Reporting Fisher's Exact Test, RFET, and the Urn Model

It was indicated above that the validity of the chi-square test of independence rests on sampling of records being multinomial, and not conditioned on a given AE. The reporting Fisher's exact test (Fisher,^[36] Ahmed, Dalmaso et al.^[27]) requires conditioning not only on a given AE, but also on a particular drug. Thus, not only is n_j fixed, but so is n_i . Here, the random variable, N_{ij} , is for the outcome n_{ij} ; it follows a hypergeometric distribution given n_i , n_j , and n . Therefore

$$P(N_{ij} = n_{ij}) = \frac{\binom{n_j}{n_{ij}} \binom{n_{j'}}{n_i - n_{ij}}}{\binom{n}{n_i}}$$

Here the quantity $\binom{n}{x} = \frac{n!}{x!(n-x)!}$ is the binomial coefficient, which represents the number of ways that x objects can be selected from n , without regards to order. A p-value for a test that the j -th AE is a signal for a disproportional rate for the i -th drug is given by $(N_{ij} \geq n_{ij})$.

The hypergeometric distribution is highly discrete for small samples, so when n_{ij} can only assume a few values, the p-value can only take on the same small number of possible values. It is therefore usually not possible to achieve the desired significance level to which the p-value is compared. To reduce conservatism, Agresti^[26] recommends the use of the mid-p-value given by

$$\text{mid-p-value} = \frac{1}{2} P(N_{ij} = n_{ij}) + P(N_{ij} > n_{ij})$$

While the probability of Type I error is no longer guaranteed to be no greater than the specified significance level, in practice it is rarely much greater (Agresti^[26]).

Hochberg, Reisinger et al.^[37] introduced the urn model under similar assumptions as those of the reporting Fisher's exact test. They define the quantity

$$U_{ij} = \frac{1}{P(N_{ij} \geq n_{ij})}$$

as a measure of statistical unexpectedness. The probability in the denominator, which is the p-value given above for Fisher's test, is evaluated conditional on the assumption of no association between the i -th drug and j -th AE. The quantity U_{ij} can therefore be thought of as a reciprocal p-value, and compared to $1/\alpha$ to assess the presence or absence of a signal.

Likelihood Ratio Test, LRT

The likelihood ratio test proposed by Huang, Zalkikar et al.^[28] compares the relative reporting rate, RRR_{ij} , of

different AEs, A_j , for $j = 1, \dots, J$ for a given drug i of interest. The test is therefore based on multiple 2×2 tables of the form given in Table 2. The null hypothesis is that for the i -th drug, $RRR_{ij} = 1$ for all $j = 1, \dots, J$, with the alternative hypothesis that $RRR_{ij} > 1$ for at least one $j = 1, \dots, J$. For drug i , the test is based on J test statistics given by

$$LRT_{ij} = \frac{\binom{n_{ij}}{n_{.j}} \binom{n_{ij'}}{n_{.j'}}}{\binom{n_{i.}}{n}} = \binom{n_{ij}}{E_{ij}} \binom{n_{ij'}}{E_{ij'}} \quad \text{for } j = 1, \dots, J$$

Let the estimates of the conditional probabilities of observing the i -th drug given that the j -th AE is/is not reported be $\hat{\pi}_{i|j} = n_{ij}/n_{.j}$ and $\hat{\pi}_{i|j'} = n_{ij'}/n_{.j'}$, respectively. For the i -th drug, the maximum likelihood test statistic for the alternative hypothesis $RRR_{ij} > 1$ for at least one $j = 1, \dots, J$ is

$$MLR_i = \max_j \left[LRT_{ij} I(\hat{\pi}_{i|j} > \hat{\pi}_{i|j'}) \right] \\ = \max_j \left[\binom{n_{ij}}{E_{ij}} \binom{n_{ij'}}{E_{ij'}} I(\hat{\pi}_{i|j} > \hat{\pi}_{i|j'}) \right]$$

where $I(\hat{\pi}_{i|j} > \hat{\pi}_{i|j'}) = 1$ if $\hat{\pi}_{i|j} > \hat{\pi}_{i|j'}$, and 0 otherwise.

The distribution of MLR_i under the null hypothesis that $RRR_{ij} = 1$ for all $j = 1, \dots, J$ is not analytically tractable, but can be estimated using Monte Carlo methods by generating a large number of simulated data sets; Huang, Zalkikar et al.^[28] create 9,999 such data sets. The simulation is based on the full $I \times J$ contingency table given in Table 1. A single simulated data set is obtained by generating values of $n_{i1}, n_{i2}, \dots, n_{iJ}$ from a multinomial distribution where the total number of trials is $n_{i.}$ and the probabilities are $n_{.j}/n$ for $j = 1, \dots, J$. Let the values obtained for the s -th simulated data set be $n_{i1}^{(s)}, n_{i2}^{(s)}, \dots, n_{iJ}^{(s)}$ for $s = 1, \dots, 9999$. For each of these simulated data sets, a value of $MLR_i^{(s)}$ is calculated. The 9,999 values obtained for MLR_i through the simulation can be used to define the empirical distribution of this statistic.

To test for AEs signaling disproportionate rates for drug i , the first step is to compare the value of MLR_i computed from the actual data to an appropriate percentile of the empirical distribution of MLR_i obtained via simulation. For illustrative purposes, suppose that we set $\alpha = 0.05$. Then if the value of MLR_i computed from the actual data exceeds the upper 5th percentile of the empirical distribution of MLR_i , then the AE corresponding to $\max_j \left[LRT_{ij} I(\hat{\pi}_{i|j} > \hat{\pi}_{i|j'}) \right]$ based on the actual data is deemed to be the most significant signal. To identify secondary signals, the AE that yielded the second largest value for $LRT_{ij} I(\hat{\pi}_{i|j} > \hat{\pi}_{i|j'})$ from the actual data is considered next. If this value also exceeds the upper 5th

percentile of the empirical distribution of MLR_i , there is evidence to suggest that this AE is also a signal. The AE associated with the next largest $LRT_{ij} I(\hat{\pi}_{i|j} > \hat{\pi}_{i|j'})$ from the actual data would be investigated next, and so on, until no further signals can be identified.

4 BAYES AND EMPIRICAL BAYES METHODS

Traditional Bayes techniques for signal detection in passive pharmacovigilance tend to focus on the relative reporting rate. In this section, both empirical and fully Bayesian methods for disproportionality analysis are presented.

Bayesian Confidence Propagation Neural Network, BCPNN

The information component

$$IC_{ij} = \log_2(RRR_{ij}) = \log_2 \left(\frac{\pi_{ij}}{\pi_{i.} \pi_{.j}} \right)$$

is the focus of the BCPNN developed by investigators at the World Health Organization (WHO) Collaborating Centre for International Drug Monitoring (Bate, Lindquist et al.^[22]). Starting from the $I \times J$ contingency table given in Table 1, $J - 2 \times 2$ tables are constructed for the i -th drug. For the i -th drug and j -th AE, beta prior distributions for the unconditional marginal and joint reporting probabilities π_{ij} , $\pi_{i.}$, and $\pi_{.j}$ are specified. Conditional on these distributions, the associated cell counts n_{ij} , $n_{i.}$, and $n_{.j}$ are assumed to be realizations from independent binomial distributions, each with a parameter n , for the number of trials. Specifically, it is assumed that

$$n_{ij} | \pi_{ij} \sim \text{Binomial}(n, \pi_{ij}) \text{ with } \pi_{ij} \sim \text{Beta}(\alpha_{ij}, \beta_{ij})$$

$$n_{i.} | \pi_{i.} \sim \text{Binomial}(n, \pi_{i.}) \text{ with } \pi_{i.} \sim \text{Beta}(\alpha_{i.}, \beta_{i.})$$

$$n_{.j} | \pi_{.j} \sim \text{Binomial}(n, \pi_{.j}) \text{ with } \pi_{.j} \sim \text{Beta}(\alpha_{.j}, \beta_{.j})$$

Given these specifications, it follows that the posterior distributions of π_{ij} , $\pi_{i.}$, and $\pi_{.j}$ are also beta, with

$$\pi_{ij} | n_{ij} \sim \text{Beta}(\alpha_{ij}^*, \beta_{ij}^*)$$

$$\pi_{i.} | n_{i.} \sim \text{Beta}(\alpha_{i.}^*, \beta_{i.}^*)$$

$$\pi_{.j} | n_{.j} \sim \text{Beta}(\alpha_{.j}^*, \beta_{.j}^*)$$

where $\alpha_{ij}^* = \alpha_{ij} + n_{ij}$, $\beta_{ij}^* = \beta_{ij} + n - n_{ij}$, $\alpha_{i.}^* = \alpha_{i.} + n_{i.}$, $\beta_{i.}^* = \beta_{i.} + n_{i.}$, $\alpha_{.j}^* = \alpha_{.j} + n_{.j}$, and $\beta_{.j}^* = \beta_{.j} + n_{.j}$. In some of the early studies of the BCPNN (Bate, Lindquist et al.^[21] Orre,

Lansner et al.^[38], starting values of one are specified for α_{ij} , α_i , and α_j , as well as for β_i and β_j . The hyperparameter β_{ij} is estimated by solving the equation that the prior mean of π_{ij} is equal to its posterior mean under the hypothesis of no association between the i -th drug and j -th AE, namely

$$\beta_{ij} = \frac{1 - E(\pi_i | n_i) E(\pi_j | n_j)}{E(\pi_i | n_i) E(\pi_j | n_j)} = \frac{1 - \frac{\alpha_i^*}{(\alpha_i^* + \beta_i^*)} \frac{\alpha_j^*}{(\alpha_j^* + \beta_j^*)}}{\frac{\alpha_i^*}{(\alpha_i^* + \beta_i^*)} \frac{\alpha_j^*}{(\alpha_j^* + \beta_j^*)}}$$

which is estimated by

$$\hat{\beta}_{ij} = \frac{(n+2)^2 - (n_i+1)(n_j+1)}{(n_i+1)(n_j+1)}$$

if α_{ij} , α_i , α_j , β_i , and β_j are all set to one.

Using the delta method, we can write

$$IC_{ij} \approx \frac{1}{\log 2} \left\{ \log \left[\frac{E(\pi_{ij} | n_{ij})}{E(\pi_i | n_i) E(\pi_j | n_j)} \right] + \frac{\pi_{ij} - E(\pi_{ij} | n_{ij})}{E(\pi_{ij} | n_{ij})} - \frac{\pi_i - E(\pi_i | n_i)}{E(\pi_i | n_i)} - \frac{\pi_j - E(\pi_j | n_j)}{E(\pi_j | n_j)} \right\}$$

which allows for the posterior mean and variance of IC_{ij} to be determined, yielding

$$\begin{aligned} E(IC_{ij} | n_{ij}) &= \log_2 \left[\frac{E(\pi_{ij} | n_{ij})}{E(\pi_i | n_i) E(\pi_j | n_j)} \right] \\ &= \log_2 \left[\frac{\frac{\alpha_{ij}^*}{(\alpha_{ij}^* + \beta_{ij}^*)}}{\frac{\alpha_i^*}{(\alpha_i^* + \beta_i^*)} \frac{\alpha_j^*}{(\alpha_j^* + \beta_j^*)}} \right] \end{aligned}$$

and

$$\begin{aligned} V(IC_{ij} | n_{ij}) &\approx \frac{1}{(\log 2)^2} \left\{ \frac{V[\pi_{ij} - E(\pi_{ij} | n_{ij})]}{[E(\pi_{ij} | n_{ij})]^2} + \frac{V[\pi_i - E(\pi_i | n_i)]}{[E(\pi_i | n_i)]^2} + \frac{V[\pi_j - E(\pi_j | n_j)]}{[E(\pi_j | n_j)]^2} \right\} \\ &\approx \frac{1}{(\log 2)^2} \left\{ \frac{\beta_{ij}^*}{\alpha_{ij}^* (\alpha_{ij}^* + \beta_{ij}^* + 1)} + \frac{\beta_i^*}{\alpha_i^* (\alpha_i^* + \beta_i^* + 1)} + \frac{\beta_j^*}{\alpha_j^* (\alpha_j^* + \beta_j^* + 1)} \right\} \end{aligned}$$

which become

$$E(IC_{ij} | n_{ij}) = \frac{1}{\log 2} \log \left[\frac{(n_{ij}+1)(n+2)^2}{(n+\beta_{ij}+1)(n_i+1)(n_j+1)} \right]$$

and

$$\begin{aligned} V(IC_{ij} | n_{ij}) &\approx \frac{1}{(\log 2)^2} \left\{ \frac{(n-n_{ij}-\hat{\beta}_{ij})}{(n_{ij}+1)(n+\hat{\beta}_{ij}+2)} + \frac{(n-n_i+1)}{(n_i+1)(n+3)} \right. \\ &\quad \left. + \frac{(n-n_j+1)}{(n_j+1)(n+3)} \right\} \end{aligned}$$

if α_{ij} , α_i , α_j , β_i , and β_j are all set to one. These quantities can be estimated by replacing β_{ij} with the estimate $\hat{\beta}_{ij}$, while allows for an approximate $100(1-\alpha)\%$ confidence interval for IC_{ij} to be specified as

$$\left(E(IC_{ij} | n_{ij}) - z_{\alpha/2} \sqrt{V(IC_{ij} | n_{ij})}, E(IC_{ij} | n_{ij}) + z_{\alpha/2} \sqrt{V(IC_{ij} | n_{ij})} \right)$$

If this interval lies entirely above zero, then the j -th AE can be interpreted as a signal of a disproportionate AE rate for the i -th drug.

Subsequent to this approximation proposed by Bate, Linquist et al.^[22], for small sample sizes, Gould^[39] presented exact expressions for the posterior mean and variance of the IC_{ij} using the moment generating function technique. These are given by

$$\begin{aligned} E(IC_{ij} | n_{ij}) &= \frac{1}{\log 2} \left\{ \Psi(\alpha_{ij}^*) - \Psi(\alpha_{ij}^* + \beta_{ij}^*) \right. \\ &\quad \left. - [\Psi(\alpha_i^*) - \Psi(\alpha_i^* + \beta_i^*) + \Psi(\alpha_j^*) - \Psi(\alpha_j^* + \beta_j^*)] \right\} \end{aligned}$$

and

$$\begin{aligned} V(IC_{ij} | n_{ij}) &= \frac{1}{(\log 2)^2} \left\{ \Psi'(\alpha_{ij}^*) - \Psi'(\alpha_{ij}^* + \beta_{ij}^*) \right. \\ &\quad \left. - [\Psi'(\alpha_i^*) - \Psi'(\alpha_i^* + \beta_i^*) + \Psi'(\alpha_j^*) - \Psi'(\alpha_j^* + \beta_j^*)] \right\} \end{aligned}$$

where $\Psi(k) = d \log \Gamma(k) / dk = \Gamma'(k) / \Gamma(k)$ is the digamma function, and $\Psi'(k) = d \Psi(k) / dk$ is the trigamma function,

both of which are extensively tabulated and available as built-in functions in many statistical software packages. The quantity $\Gamma(k)$ is the gamma function, defined as

$$\Gamma(k) = \int_0^{\infty} x^{k-1} e^{-x} dx$$

This function has the properties that $\Gamma(1) = 1$ and, provided that k is an integer, $\Gamma(k) = (k-1)!$. We note that the corresponding formulas based on the moment generating technique give approximately the same results for large samples.

Gould^[39] also suggested using a less concentrated prior density for π_{ij} that is independent of the observed values for π_i and π_j by replacing these two marginal probabilities with their a priori expected values $E(\pi_i) = \alpha_i / (\alpha_i + \beta_i)$ and $E(\pi_j) = \alpha_j / (\alpha_j + \beta_j)$. Under this replacement, the prior distribution for π_{ij} is beta with parameters α_{ij} and

$$\beta_{ij} = \frac{1 - E(\pi_i)E(\pi_j)}{E(\pi_i)E(\pi_j)} = \frac{1 - \frac{\alpha_i}{(\alpha_i + \beta_i)} \frac{\alpha_j}{(\alpha_j + \beta_j)}}{\frac{\alpha_i}{(\alpha_i + \beta_i)} \frac{\alpha_j}{(\alpha_j + \beta_j)}} = \frac{(\alpha_i + \beta_i)(\alpha_j + \beta_j) - \alpha_i \alpha_j}{\alpha_i \alpha_j}$$

If the same starting values of one as specified above for α_{ij} , α_i , α_j , β_i , and β_j are used, then $\beta_{ij} = 3$.

More recently, Noren, Bate et al.^[40] pointed out that π_{ij} , π_i , and π_j are not necessarily independent as the above analysis assumes, and proposed a full Dirichlet distribution as the multivariate prior distribution of the vector of joint probabilities $\pi' = (\pi_{ij}, \pi_{ij'}, \pi_{i'j}, \pi_{i'j'})$. For a particular 2×2 table, setting $i = 1$, $i' = 0$, $j = 1$, and $j' = 0$, yields $\pi' = (\pi_{11}, \pi_{10}, \pi_{01}, \pi_{00})$ with parameters $\alpha_{ij} = q_i q_j \alpha$ where $q_i = (n_i + 0.5) / (n + 1)$, $q_j = (n_j + 0.5) / (n + 1)$, and $\alpha = 0.5 / q_1 q_1$ for $i, j = 0, 1$. Since, along with the quantity n , the vector π' contains the parameters of the multinomial distribution characterizing the prior distribution of the random vector $(n_{11}, n_{10}, n_{01}, n_{00})'$, this leads to a posterior Dirichlet distribution for π' with parameters $\gamma_{ij} = \alpha_{ij} + n_{ij}$ for $i, j = 0, 1$, and beta distributions for the marginal distributions of π_{11} , $\pi_{1\cdot}$, and $\pi_{\cdot 1}$. For additional details, the reader is referred to Noren, Bate et al.^[40]

Multi Gamma Poisson Shrinker, MGPS

The MGPS approach, proposed by DuMouchel,^[20] and DuMouchel and Pregibon^[21], also considers the information component, $IC_{ij} = \log_2(RRR_{ij})$. It is based on the assumption that the number of reports, n_{ij} , of the j -th AE with the i -th drug, $i = 1, \dots, I$ and $j = 1, \dots, J$, are independent Poisson random variables with means $\mu_{ij} = \lambda_{ij} \times E_{ij}$,

where $\lambda_{ij} = RRR_{ij}$, the relative reporting ratio, and E_{ij} is the expected value of n_{ij} when $RRR_{ij} = 1$. As indicated in the previous discussion of frequentist methods, the relative reporting ratio is estimated by n_{ij} / E_{ij} ; thus an estimate for $\lambda_{ij} = RRR_{ij}$ in excess of one would imply that the observed frequency of the i -th drug and j -th AE pair exceeds what would be expected under independence. However, in the Bayesian approach, rather than treating the λ_{ij} as constants, each is assumed to be drawn independently from a common prior distribution, which is assumed to be a mixture of two gamma distributions. The family of gamma distributions have a conjugate relationship with the Poisson distribution, making them a convenient choice for this purpose. Specifically, the probability density function for a gamma random variable, λ , with mean α/β and variance α/β^2 is given by

$$f(\lambda; \alpha, \beta) = \beta^\alpha \lambda^{\alpha-1} e^{-\beta\lambda} / \Gamma(\alpha)$$

and the prior probability density function of λ_{ij} is

$$f(\lambda_{ij}; \alpha_0, \beta_0, \alpha_1, \beta_1, P) = Pf(\lambda_{ij}; \alpha_0, \beta_0) + (1 - P)f(\lambda_{ij}; \alpha_1, \beta_1)$$

According to DuMouchel,^[20] “the exact choice of the prior distribution for $[\lambda_{ij}]$ is not so important as that it have several free parameters so that the distribution of $[\lambda_{ij}]$ can be fit using observed data.”

Under these assumptions, the marginal distribution of n_{ij} is a mixture of negative binomial distributions; namely

$$f(n_{ij}; \alpha_0, \beta_0, \alpha_1, \beta_1, P, E_{ij}) = Pf\left(n_{ij}; \alpha_0, \frac{E_{ij}}{\beta_0 + E_{ij}}\right) + (1 - P)f\left(n_{ij}; \alpha_1, \frac{E_{ij}}{\beta_1 + E_{ij}}\right)$$

Where

$$f\left(n_{ij}; \alpha, \frac{E_{ij}}{\beta}\right) = \binom{\alpha + n_{ij} - 1}{n_{ij}} \left(\frac{E_{ij}}{\beta + E_{ij}}\right)^{n_{ij}} \left(1 - \frac{E_{ij}}{\beta + E_{ij}}\right)^{\alpha-1}$$

The posterior distribution of λ_{ij} remains a mixture of gamma distributions, but with modified parameters. Let Q be the posterior probability that λ_{ij} comes from the first component of the mixture distribution, given n_{ij} . Then, from Bayes rule,

$$Q = \frac{pf\left(n_{ij}; \alpha_0, \frac{E_{ij}}{\beta_0 + E_{ij}}\right)}{pf\left(n_{ij}; \alpha_0, \frac{E_{ij}}{\beta_0 + E_{ij}}\right) + (1 - P)f\left(n_{ij}; \alpha_1, \frac{E_{ij}}{\beta_1 + E_{ij}}\right)}$$

This yields

$$f(\lambda_{ij}|n_{ij}) = Qf(\lambda_{ij}; \alpha_0 + n_{ij}, \beta_0 + E_{ij}) \\ + (1-Q)f(\lambda_{ij}; \alpha_1 + n_{ij}, \beta_1 + E_{ij})$$

as the posterior probability distribution of λ_{ij} given n_{ij} .

Maximum likelihood estimates of the five parameters $(\alpha_0, \hat{\beta}_0, \alpha_1, \beta_1, P)$ can be obtained using numerical methods, which can be computationally intensive. Since the parameters are estimated, the approach is empirical Bayes in nature. Once these estimates have been obtained, the posterior mixing parameter Q can also be estimated. The posterior means and variances of λ_{ij} are

$$E(\lambda_{ij}|n_{ij}) = \hat{Q} \frac{\hat{\alpha}_0 + n_{ij}}{\hat{\beta}_0 + E_{ij}} + (1 - \hat{Q}) \frac{\hat{\alpha}_1 + n_{ij}}{\hat{\beta}_1 + E_{ij}}$$

and

$$V(\lambda_{ij}|n_{ij}) = \hat{Q} \frac{\hat{\alpha}_0 + n_{ij}}{(\hat{\beta}_0 + E_{ij})^2} + (1 - \hat{Q}) \frac{\hat{\alpha}_1 + n_{ij}}{(\hat{\beta}_1 + E_{ij})^2}$$

Bearing in mind the information component $IC_{ij} = \log_2(RRR_{ij}) = \log_2(\lambda_{ij})$, the delta method allows us to write

$$E[\log_2(\lambda_{ij}|n_{ij})] \approx \log_2 E(\lambda_{ij}|n_{ij})$$

and

$$V[\log_2(\lambda_{ij}|n_{ij})] \approx \frac{1}{(\log 2)^2} \frac{V(\lambda_{ij}|n_{ij})}{[E(\lambda_{ij}|n_{ij})]^2}$$

This leads to the $100(1 - \alpha)\%$ confidence interval for λ_{ij} given by

$$\left(\exp \left[EBGM(\lambda_{ij}) - z_{\alpha/2} \frac{\sqrt{V(\lambda_{ij}|n_{ij})}}{E(\lambda_{ij}|n_{ij})} \right], \exp \left[EBGM(\lambda_{ij}) + z_{\alpha/2} \frac{\sqrt{V(\lambda_{ij}|n_{ij})}}{E(\lambda_{ij}|n_{ij})} \right] \right)$$

where $EBGM(\lambda_{ij}) = \log_2 E(\lambda_{ij}|n_{ij})$ is the empirical Bayes geometric mean of λ_{ij} . To assess whether the j -th AE can be interpreted as a signal of a disproportionate rate for the i -th drug, DuMouchel and Pregibon^[21] suggest using the fifth percentile of the distribution of $EBGM(\lambda_{ij})$, known as EB05, to rank signals by order of ‘interestingness’. For $n_{ij} > 0$, Szarfman, Machado et al.^[41] recommend a comparison of this percentile to a value of two to assess whether the j -th AE can be interpreted as a signal of a disproportionate rate for the i -th drug. For commonly-encountered situations

in which a significant number of the n_{ij} in the $I \times J$ table presented in Table 1 are zero, to ease computing time DuMouchel and Pregibon^[21] provide a modified likelihood that results from replacing the unconditional densities in $f(n_{ij}; \alpha_0, \beta_0, \alpha_1, \beta_1, P, E_{ij})$ by densities that are conditional

on $n_{ij} \geq n^*$, say. Specifically, $f\left(n_{ij}; \alpha_k, \frac{E_{ij}}{\beta_k + E_{ij}}\right)$ for $k = 0, 1$ are replaced by

$$f\left(n_{ij}; \alpha_k, \frac{E_{ij}}{\beta_k + E_{ij}}\right) / \left(1 - \sum_{m=0}^{n^*-1} f\left(m; \alpha_k, \frac{E_{ij}}{\beta_k + E_{ij}}\right)\right)$$

This replacement also yields the correct likelihood function for deriving maximum likelihood estimates when a minimum level of n^* is placed on n_{ij} .

Noren and Edwards^[42] introduced another IC_{ij} measure by also treating the number of reports n_{ij} , of the j -th AE with the i -th drug, $i = 1, \dots, I$ and $j = 1, \dots, J$, as independent Poisson random variables with means $\mu_{ij} = \lambda_{ij} \times E_{ij}$, with $\lambda_{ij} = RRR_{ij}$. The λ_{ij} are assumed to be independent with a gamma prior distribution $f(\lambda_{ij}; \alpha, \beta)$ with $\alpha = 0.5$ and $\beta = 0.5$, namely

$$f(\lambda_{ij}; 0.5, 0.5) = \frac{1}{\Gamma(0.5)\sqrt{2}} \lambda_{ij}^{-0.5} e^{-0.5\lambda_{ij}}$$

The posterior distribution of λ_{ij} given n_{ij} is also gamma. However, instead of $\alpha = 0.5$ and $\beta = 0.5$, the parameters are $0.5 + n_{ij}$ and $0.5 + E_{ij}$, respectively, so that

$$E[\log_2(\lambda_{ij}|n_{ij})] \approx \log_2 E(\lambda_{ij}|n_{ij}) = \log_2 \frac{0.5 + n_{ij}}{0.5 + E_{ij}}$$

It is instructive to compare this result to the estimate of IC_{ij} obtained under the frequentist approach; namely

$$\widehat{IC}_{ij} = \log_2 \left(\frac{n_{ij}}{E_{ij}} \right)$$

Note that the result of Noren and Edwards^[42] simply adds 0.5 to the numerator and denominator of the frequentist expression, which results in shrinkage towards $IC_{ij} = 0$. These authors state that “the impact is equivalent to that of ½ additional expected events, and an exactly matching increase in the observed number.” Noren, Bate et al.^[40] and

Noren, Sundberg et al.^[43] successfully applied this shrinkage strength to pattern discovery in the analysis of large collections of individual case safety reports.

Using the gamma posterior distribution for λ_{ij} given n_{ij} , credibility interval limits for λ_{ij} can be found numerically as solutions to the following equation for appropriate posterior quantiles (p):

$$\int_0^{\lambda_{ij}(p)} \frac{(0.5 + E_{ij})^{0.5+n_{ij}}}{\Gamma(0.5 + n_{ij})} \lambda_{ij}^{(0.5+n_{ij})-1} e^{-(0.5+n_{ij})\lambda_{ij}} d\lambda_{ij} = p$$

Noren and Edwards^[42] suggest setting $p = 0.025$ and $p = 0.975$ and specify the resulting values of $\lambda_{ij}(0.025)$ and $\lambda_{ij}(0.975)$ as the bounds of a two-sided 95% credibility interval for λ_{ij} . Since $IC_{ij} = \log_2(\lambda_{ij})$, this interval can then be transformed to one for the information component.

More recently, Huang, Zalkikar et al.^[44] introduced a simplified Bayes method that, similar to Noren and Edwards,^[42] also imposes a gamma prior distribution on λ_{ij} . Huang, Zalkikar et al.^[44] set $\alpha = \beta$, after specifying $0 < \alpha < 1$. Three choices of α selected were 0.5, 0.01, and 0.0001. The case where $\alpha = 0.5$ corresponds to a continuous uniform prior over (0, 1), which the authors described as the informative case. The other two cases were depicted as less informative, and non-informative, respectively.

The approaches of Noren and Edwards^[42] and Huang, Zalkikar et al.^[44] are fully Bayesian since the parameters of the gamma prior distribution are specified. By contrast, the BCPNN and MGPS methods are empirical Bayes in nature as these parameters are estimated.

5 ISSUES IN THE USE OF DISPROPORTIONALITY METHODS FOR SIGNAL DETECTION

When disproportionality methods are used for signal detection, there are a number of important issues that require careful contemplation. Two of the most commonly considered ones are discussed here; the choice of a signal threshold level, and the control of the Type I error rate when a number of drug/adverse event pairs are simultaneously investigated.

Signal Threshold Level

There has been much discussion in the literature on passive pharmacovigilance regarding the criteria that have been proposed to identify signals of adverse drug reactions. Historically, such criteria have been based on judgment about whether the estimated risk of an AE is sufficiently large to conclude that a signal is present. A decision is often made by determining if the lower bound of a confidence or credible interval indicates a significant increase in reporting rate over what would be expected under no

association. For example, in the above discussion of the proportional reporting ratio as one of the frequentist measures of disproportionality for signal detection, an approximate $100(1-\alpha)\%$ confidence interval was presented for this measure, and it was proposed that evidence of a signal would prevail if the lower limit of this interval exceeded one.

While a threshold level of unity appears reasonable when risk is measured in relative terms (on a log scale this cutoff value would be transformed to zero), not all studies involving such disproportionality methods abide by this criteria. In fact, Hauben, Madigan et al.^[45] point out that “there is currently no theoretical basis or firm empirical support establishing universal thresholds [for] defining a potential signal.” This lack of a theoretical basis is apparent when methodologies are compared. Ahmed, Haramburu et al.^[46] reiterate this point, noting that “all the proposed methods are based on arbitrary thresholds for signal generation where decision rules are not defined by any error-limiting constraint.”

An interesting study conducted by Deshpande, Gogolak et al.^[47] provides further evidence of a lack of universal agreement regarding signal detection thresholds. These authors performed a literature review to determine what thresholds were being used for signal detection in disproportionality methods. While documenting that the PRR, ROR, MGPS, and BCPNN were the most commonly used approaches, there was substantial variation in the threshold level used for each method. For example, the PRR, the most frequently-employed measure in the literature that was identified, also demonstrated the greatest variation in threshold levels to define a signal. Critical values of the PRR ranged from 1 to 3, including values 1, 1.5, 2, and 3. A number of investigations that used the PRR also required a chi-square test statistic to exceed a certain value (typically 4), with some added conditions for minimum values of n_{ij} . This latter requirement was also inconsistently applied from study to study, with the minimum being specified by different authors to be 2, 3, or higher.

For studies that use more than one disproportionality method for signal detection, it is important to note that while each method maintains a specified Type I error rate, the overall error rate will be greater, since two criteria must simultaneously hold in order to conclude that there is evidence of a signal. This needs to be taken into account when setting the individual Type I error rates for each method in order to ensure that the overall Type I error for signal detection is at the desired level.

In a similar vein, Huang, Guo et al.^[3] warn that the disproportionality methods described above “are not meant for analyzing multiple AEs for signals simultaneously. If that is the goal, one may use [a] Bonferroni correction formula (a family-wise error rate procedure) for preserving the overall Type I error; however, [if the number of AEs in the $I \times J$ table summary of the spontaneous reporting

data of interest is extremely large; for example, exceeding ten thousand as in the FAERS database], the Bonferroni tests would be very conservative.” As such, this Bonferroni family-wise error rate (FWER) has been deemed overly stringent for many applications. Benjamini and Hochberg^[29] describe some of the difficulties with FWER that result in its underutilization, and propose to control instead the expected proportion of errors among rejected hypotheses of no signal. They refer to this expected error proportion as the false discovery rate, FDR, which is described below.

False Discovery Rate

Consider the problem of simultaneously testing m hypotheses. For example, focusing on the $I \times J$ table summary of spontaneous reporting data, suppose we use the chi-square test of independence to investigate whether the j -th AE can be interpreted as a signal of a disproportionate rate for the i -th drug, for $i = 1, \dots, I$ and $j = 1, \dots, J$. As such, the particular m hypotheses to be tested are known in advance. For each of the m hypotheses, unknown to us, either the null hypothesis of independence between the drug and AE is true or not. When we test, we either reject or do not reject this null hypothesis, and in doing so, we could be correct, or in error. These various outcomes can be summarized in the following 2×2 table, where it is assumed that m_0 of the null hypotheses are true.

Note that while r can be ascertained upon completion of testing the m hypotheses, the values of u , v , t , and s are unknown since we do not know the true state in any of the tests. Therefore, defining R to be a random variable with observed value r , and U , V , T , and S as unobservable random variables associated with u , v , t , and s in the table, then $\text{FWER} = P(V \geq 1)$. Testing each individual null hypothesis at level α guarantees that $(V/m) \leq \alpha$, while testing each at level α/m guarantees that $P(V \geq 1) \leq \alpha$.

The proportion of errors committed when the null hypothesis is rejected (the proportion of times that the null hypothesis is rejected when it is true) can be viewed through the random variable $W = V/(V + S)$. Benjamini and Hochberg^[29] define the false discovery rate, FDR, as the expected value of W , given by

$$\text{FDR} = E(W) = E\left(\frac{V}{V + S}\right) = E\left(\frac{V}{R}\right)$$

Table 4 Summary of the results of m simultaneous hypothesis tests

True State	Test Result		Total
	Null Not Rejected	Null Rejected	
Null Hypothesis True	u	v	m_0
Null Hypothesis False	t	s	$m - m_0$
Total	$m - r$	r	m

To avoid division by zero, Benjamini and Hochberg^[29] propose an alternative formulation of the FDR in which there is conditioning on at least one null hypothesis being rejected ($R > 0$), namely

$$\text{FDR} = E\left(\frac{V}{R} | R > 0\right) P(R > 0)$$

Note that when all the null hypotheses are true, and $m_0 = m$, the FDR is equivalent to the FWER. However, if $m_0 < m$, the $\text{FDR} \leq \text{FWER}$. Therefore in this situation, a multiple testing procedure that controls the FDR at some level w^* , say, will be less stringent, making it more likely that true signals where the null hypothesis is false will be correctly detected, with a concomitant gain in power.

Returning to the example where m multiple hypothesis chi-square tests of independence are to be conducted, the FDR can be controlled at some specified level w^* as follows. Let H_l represent the l -th hypothesis to be tested, $l = 1, \dots, m$. Consider testing $H_1, \dots, H_m$ based on the corresponding p-values, which we shall denote as $P_1, \dots, P_m$. Let $P_{(1)} \leq P_{(2)} \leq \dots \leq P_{(m)}$ be the ordered p-values, and $H_{(l)}$ be the null hypothesis corresponding to $P_{(l)}$. If k is defined as the largest integer l for which $P_{(l)} \leq \frac{l}{m} w^*$, then the decision to reject all (l) for $l = 1, \dots, k$ will control the FDR at w^* .

Note that although the illustration above was presented in the context of the chi-square test for independence, the FDR can be controlled in the same fashion for other frequentist and Bayesian approaches that rely on confidence or credible intervals. As an example, consider the ROR, with a corresponding confidence interval based on the standard normal distribution. Suppose we wish to conduct m tests of hypothesis involving I drugs and J AEs, where, for the i -th drug and j -th AE, we wish to test the null hypothesis that $\text{ROR}_{ij} = 1$ (or $\log(\text{ROR}_{ij}) = 0$). The p-value for this test is given by

$$\text{p-value} = 2P\left[Z \geq \log(\widehat{\text{ROR}}_{ij}) / \sqrt{V[\log(\widehat{\text{ROR}}_{ij})]}\right]$$

While it is possible to determine appropriate p-values for the other disproportionality methods in a similar manner, it is also worth noting that the LRT proposed by Huang, Zalkikar et al.^[28] is able to control the FDR, as well as the overall Type I error rate.

Ahmed, Haramburu et al.^[46] Ahmed, Dalmasso et al.^[27] and Ahmed, Thiessard et al.^[35] describe the use of the FDR in various pharmacovigilance applications. They also note that since the seminal paper of Benjamini and Hochberg,^[29] a number of procedures have been proposed to estimate the FDR, citing an approach based on assuming a mixture model for the marginal distribution of the p-values resulting from the m tests of hypothesis as a particularly popular approach. Techniques for estimating the FDR employing this strategy include the q-value approach (Storey,^[48]

Storey,^[49] and Storey and Tibshirani^[50]); the method of Pounds and Morris,^[51] which assumes a beta-uniform mixture (BUM) for the marginal distribution of the p-values (BUM); the spacings LOESS histogram (SPLOSH) introduced by Pounds and Cheng^[52] (2004); and an general class of estimators proposed by Dalmasso, Broet et al.^[53] known as location based estimators (LBE).

It is worth noting that clinical AE data can be affected by another form of multiplicity. Adverse events have certain biological relationships within the context of the body system. Ignoring such biological structure may result in a loss of control over the FDR. Mehrotra and Heyse^[54] propose a two-step application of adjusted p-values based on the Benjamini and Hochberg^[29] approach. Alternatively, Berry and Berry^[55] subdivide the set of all AEs into body systems and apply a three level fully Bayesian model to the log odds ratio of patients receiving the *i*-th drug who are experiencing the *j*-th AE relative to patients who experiencing a particular AE, but not receiving the *i*-th drug. While these two methods were developed with clinical rather than SR data in mind, such data are relevant to the overall weight of evidence in support of a possible AE.

6 DISCUSSION

This article provides an overview of the most commonly-used passive-surveillance disproportionality methods for the detection of adverse events associated with the use of pharmaceutical products in spontaneous reporting databases. Both frequentist and Bayesian approaches are described. For each method, we describe how the technique can be applied for the purpose of signal detection using spontaneous reporting data. Important considerations in such applications are the choice of the signal threshold level, and control of the Type I error and false discovery rate when testing multiple hypotheses.

It is worth noting that various software packages are available for the application of most of the disproportionality methods summarized above. These include the JMP Clinical software from SAS^[56], an R package entitled *PhViD*, which serves as an acronym for pharmacovigilance signal detection (Ahmed and Ponset^[57]), and the software from the Observational Medical Outcomes Partnership (OMOP)^[16] methods library. The approaches covered by these packages include the reporting odds ratio, the proportional reporting ratio, reporting Fisher's exact test, the Bayesian confidence propagation neural network, and the multi Gamma Poisson shrinker.

A number of issues may arise when applying the disproportionality methods summarized above. Spontaneous reporting data is retrospective in nature: conditional on AE status, the drugs that the individual was taking in advance of making the report are observed. Spontaneous reporting data should therefore be analyzed as such.

The voluntary nature of SR data can result in under-reporting of AEs experienced by patients taking the drug of interest. The effects of under-reporting have been discussed in the literature (van der Heijden, Van Puijenbroek et al.,^[58] Hazell and Shakir^[59]), and methods for bias correction when using the PRR and ROR with supplementary information have been suggested (Ghosh and Dewanji^[60]). When describing the underlying mechanism responsible for SR data, in addition to the drug/AE relationship, Roux, Thiessard et al.^[31] acknowledged the effects of a number of factors, including the background incidence of the AE, the background drug exposure frequency, and the probability that the event is reported. All of these factors contribute to the potential for underreporting of a safety issue.

Disproportionality methods focus solely on the occurrence of the *j*-th AE with the *i*-th drug within a spontaneously generated safety report, without taking into account external factors such as co-morbidity. An excellent summary of the challenges encountered in the interpretation of the results from disproportionality approaches is given by van Manen, Fram et al.^[61] They highlight Simpson's paradox (Simpson^[62]), signal leakage (also known as 'signal absorption', or 'confounding by association'), confounding by indication, and masking as important issues to be considered when interpreting analysis of SR databases.

Simpson's paradox may manifest if an AE is more prevalent in a subgroup of the population that is also more likely to be exposed to a particular drug. Application of disproportionality methods to the general population in this case may suggest that the drug/AE combination occurs more frequently than expected. Stratification (cf. Mantel and Haenszel^[63]) is one approach that has been proposed to address this issue, where disproportionality measures are applied to each subgroup (or stratum), and then combined afterwards. A number of authors have considered extensions to disproportionality methods that involve stratification. For example, Huang, Zalkikar et al.^[27] describe a stratified analysis for the likelihood ratio test.

Consider further the situation in which two drugs are often administered together when treating a particular condition, and that one of the drugs is known to be related to a specific AE. Confounding by association may occur if application of disproportionality methods suggest that the other drug is also related to the AE due to the higher-than-expected joint occurrence of the two drugs. The statistical methods proposed by Noren, Sundberg et al.^[42] for evaluating drug-drug interactions in a surveillance context may be useful in addressing this issue. Another form of confounding (by indication) may occur when the AE is not associated with another drug, but rather with the disease being treated (Psaty, Koepsell et al.,^[64] Abrahamowicz, Bjerre et al.^[65]). Finally, masking refers to a situation where the association between a particular drug and AE is artificially diminished as a result of the fact that the database consists of other drugs that are observed with the same AE, but in much larger numbers (Maignen,

Hauben et al.^[66,67]). Some simple strategies for unmasking in ADR surveillance are discussed by Juhlin, Ye et al.^[68].

While active pharmacovigilance will play an increasing important role in drug safety evaluation in the future, passive pharmacovigilance remains an important tool for the early detection of safety signals (Chakravarty, Izem et al.^[16]). Of late, disproportionality methods have been extended to SR data with a longitudinal component. For example, Noren, Hosptadius et al.^[69] applied the fully Bayesian IC approach to study the temporal pattern discovery in longitudinal electronic patient records, while Schuemie^[70] (2011) proposed a longitudinal gamma Poisson shrinker. For additional details, see Zorych, Madigan et al.^[71] for an in-depth evaluation of different disproportionality methods for longitudinal observational databases.

ACKNOWLEDGEMENTS

The authors are grateful to the editor and a referee for useful comments on this manuscript. The research program of Patrick J. Farrell is supported by a grant from the Natural Sciences and Engineering Research Council. Christopher A. Gravel holds a Mitacs postdoctoral fellowship at McGill University, in partnership with Risk Sciences International. Slope Approach: Assessment of Dose Proportionality and Linearity Under a Crossover Design

Bin Cheng

Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

Slope Approach for Assessment of Dose Proportionality/Linearity Under a Crossover Design In this entry, we consider tests for assessment of dose proportionality/linearity under a general crossover design based on the slope approach idea.

INTRODUCTION

In pharmaceutical research and development, dose response studies are often conducted not only to assess drug tolerance and safety in Phase I clinical development but also to characterize drug–response curve with respect to efficacy in phase II clinical development. Rodda et al.^[1] indicated that the clinical investigation of the dose–response curve can be classified into categories of (1) dose ranging study, which estimates the minimum effective dose and maximum tolerable dose; (2) dose response existence; and (3) dose response characterization, which describes the shape of the dose–response relationship and decides whether there is a clinically meaningful increase in response between the minimum and maximum effective doses. Ruberg^[2,3] provided a comprehensive review of design considerations, analysis, and interpretations of dose–response studies.

OVERVIEW

In practice, it is of interest to determine the relationship between the pharmacokinetic parameters and dose levels within a clinical relevant dose range (e.g., the range between the minimum effective dose and maximum tolerable dose). If the relationship is linear, the rate of change in pharmacokinetic parameters, which are commonly used to measure the rate and extent of drug absorption over a given range, is a constant. In this case, the dose curve is said to have a linearity property. Under dose linearity, the pharmacokinetic effect of a dose change can be predicted and the dose can be adjusted accordingly to achieve the optimal/desired magnitude of effect. If, in addition to dose linearity, the dose curve also passes the origin, then it is said to have a proportionality property. Under dose proportionality, the pharmaceutical parameter changes in direct proportion to

the dose level. Dose proportionality is stronger and often more desirable than dose linearity. However, dose linearity has its own merits. First, it is often the first step toward dose proportionality, and is consequently easier to establish. Second, dose linearity is often sufficient enough for making prediction about the pharmacokinetic parameter at a given dose level. Thus dose linearity studies over a given dose range have become increasingly important in pharmaceutical research and development.

In practice, dose proportionality or linearity could be conducted under a parallel-group design, a crossover design, or a combination of a parallel-group and a crossover design. For a parallel-group design, subjects are randomly assigned to one of the L dose groups being studied. Each subject will only receive the assigned dose level once. For a $K \times J$ crossover design, subjects are randomly assigned to one of the K sequences of dose levels. Each subject will receive different dose levels at J dosing periods. A sufficient length of washout is usually applied between dose levels. In many cases, when L , the number of dose levels being studied, is greater than K , the number of dosing periods, an incomplete block crossover design is often considered. In other words, each subject will not receive all the L dose levels but J dose levels at different dosing periods. Unlike a parallel-group design, the assessment of dose linearity under a crossover design has the following complications. First, the responses from each subject are not independent. Second, the variabilities associated with the dose levels may proportionally increase with respect to the dose levels. For more information about the crossover designs and their applications, see Refs. [4–6] and the references therein.

In this entry, we consider tests for assessment of doseproportionality/linearity under a general crossover design based on the slope approach idea suggested by Chow and Liu.^[4] In the next section, a statistical model under a

$K \times J$ crossover design and the idea of slope approach are introduced. An asymptotically valid test is derived in “Tests for Dose Proportionality/Linearity.” Formulas for sample size calculation based on a prestudy power analysis under the $K \times J$ crossover design are derived in “Sample Size Calculation.” A test for departure from linearity is given in “Test for Departure from Linearity.” To illustrate the tests in this entry, an example is considered in “An Example.” And some concluding remarks are made in the last section.

STATISTICAL MODEL AND SLOPE APPROACH

Let Y_{ijk} be the response of the i th subject in the k th sequence in the j th dosing period, where $i = 1, \dots, n_k$, $j = 1, \dots, J$, and $k = 1, \dots, K$. And let $D_1, \dots, D_L$ be the dose levels being studied. Because the design is an *incomplete* block crossover design, we have to introduce the following indicators to describe the model. For each fixed j, k , and l , define δ_{jkl} to be 1 if the j th dosing period of the k th sequence has dose level D_l ; otherwise $\delta_{jkl} = 0$. Let $X_{jk} = \sum_{l=1}^L \delta_{jkl} D_l$, then X_{jk} is nothing but the actual dose level received by patients at the j th dosing period of the k th sequence. The following repeated measure model is considered:

$$Y_{ijk} = \mu_{jk} + X_{jk}(e_{ik} + \varepsilon_{ijk}) \quad (1)$$

where $X_{jk}e_{ik}$ is used to model the random effect of the k th sequence and $X_{jk}\varepsilon_{ijk}$ is used to model the random errors. We assume that e_{ik} 's are independent, identically distributed (i.i.d.) as a normal random variable with mean 0 and variance σ_s^2 , i.e., $N(0; \sigma_s^2)$, ε_{ijk} 's are i.i.d. normally distributed as $N(0; \sigma_e^2)$, and e_{ik} 's and ε_{ijk} 's are mutually independent. For simplicity, we assume that there are no carryover effects. Note that statistical models for assessment of dose proportionality/linearity as described by Chow and Liu^[4] are special cases of the above model. For example, when $J = 1$, the above model reduces to a model for parallel group design. One important assumption made here is that the standard deviation of the dose response is proportional to the dose level. This assumption is reflected in model 1 as we have $\text{Var}(Y_{ijk}) = X_{jk}^2(\sigma_s^2 + \sigma_e^2)$.

Let μ_l be the mean response at the dose level D_l . Define

$$\theta_l = \frac{\mu_{l+1} - \mu_l}{D_{l+1} - D_l}, \quad \text{for } l = 1, \dots, L-1$$

$$\mathbf{M} = \begin{pmatrix} D_3 - D_2 & D_1 - D_3 & D_2 - D_1 & & & \\ & D_4 - D_3 & D_2 - D_4 & D_3 - D_2 & & \\ & & \ddots & & & \\ & & & D_L - D_{L-1} & D_{L-2} - D_L & D_{L-1} - D_{L-2} \end{pmatrix}_{(L-2) \times L} \quad (4)$$

then it is easy to see that $\theta_1, \dots, \theta_{L-1}$ are the adjacent slopes of the dose-response curve at dose level $D_1, \dots, D_L$. The hypotheses of dose linearity can then be formulated as

$$H_0: \theta_1 = \dots = \theta_{L-1} \quad \text{vs.} \quad H_1: H_0 \text{ is not true} \quad (2)$$

Failure to reject the null hypothesis of equal slopes would lead to the conclusion of dose linearity within the dose range under study.

If we define $\theta_0 = \mu_1/D_1$, then the hypotheses of dose proportionality are

$$H_0: \theta_0 = \theta_1 = \dots = \theta_{L-1} \quad \text{vs.} \quad H_1: H_0 \text{ is not true} \quad (3)$$

TESTS FOR DOSE PROPORTIONALITY/LINEARITY

Under model 1 as described above, a test for assessment of dose proportionality/linearity within the dose range under study can be derived. In this section, we give the derivation for testing the dose linearity (Eq. 2). The derivation for testing the dose proportionality (Eq. 3) is quite similar.

Define

$$\mu = (\mu_1, \dots, \mu_L)'$$

and (see Eq. 4 below).

Then, the hypotheses in Eq. 2 is equivalent to

$$H_0: \mathbf{M}\mu = 0, \quad \text{vs.} \quad H_1: \mathbf{M}\mu \neq 0 \quad (5)$$

Define

$$\hat{\mu}_l = \sum_{j=1}^J \sum_{k=1}^K \delta_{jkl} \bar{Y}_{jk}, \quad \hat{\mu} = (\hat{\mu}_1, \dots, \hat{\mu}_L)' \quad (6)$$

where $\bar{Y}_{jk} = 1/(n_k) \sum_{i=1}^{n_k} Y_{ijk}$. It can be shown that $\hat{\mu}$ has a multivariate normal distribution with mean μ and covariance matrix Σ , where

$$\Sigma_{ll} = \sum_{k=1}^K \left(\sum_{j=1}^J \delta_{jkl} X_{jk} \right)^2 \frac{\sigma_s^2}{n_k} + \sum_{k=1}^K \sum_{j=1}^J \delta_{jkl} X_{jk}^2 \frac{\sigma_e^2}{n_k} \quad (7)$$

and for $l \neq l'$

$$\Sigma_{ll'} = \sum_{k=1}^K \left(\sum_{j=1}^J \sum_{j'=1}^J \delta_{jkl} \delta_{j'kl'} X_{jk} X_{j'k} \right) \frac{\sigma_s^2}{n_k} + \sum_{k=1}^K \sum_{j=1}^J (\delta_{jkl} \delta_{jkl'} X_{jk}^2) \frac{\sigma_e^2}{n_k} \quad (8)$$

By applying the techniques described in Section 3.2 of Ref. [7] to the ratios Y_{ijk}/X_{jk} , $i = 1, \dots, n_k$; $j = 1, \dots, J$; $k = 1, \dots, K$, consistent estimators of σ_s^2 and σ_e^2 , denoted as $\hat{\sigma}_s^2$ and $\hat{\sigma}_e^2$, respectively, can be obtained. This leads to the following asymptotic test for Eq. 5 and hence for Eq. 2.

Theorem A. Let $\hat{\Sigma}$ be the estimator of Σ by replacing σ_s^2, σ_e^2 with $\hat{\sigma}_s^2, \hat{\sigma}_e^2$, respectively. Define

$$T = \hat{\mu}' \mathbf{M}' (\mathbf{M} \hat{\Sigma} \mathbf{M}')^{-1} \mathbf{M} \hat{\mu} \quad (9)$$

then an asymptotic level α test rejects H_0 in Eq. 5 if and only if $T > \chi_{L-2, \alpha}^2$, where $\chi_{m, \alpha}^2$ is the $(1 - \alpha)$ th percentile of a chi-square random variable with degrees of freedom m .

Proof: Note that $\hat{\mu}$ defined in Eq. 6 has a multivariate normal distribution. It is seen that the mean of $\hat{\mu}$ is μ , and the components of its covariance matrix Σ are determined as Eqs. [7 and 8] based on model 1. Then $\mathbf{M} \hat{\mu}$ has a multivariate normal distribution with mean $\mathbf{M} \mu$ and covariance matrix $\mathbf{M} \Sigma \mathbf{M}'$; therefore $\hat{\mu}' \mathbf{M}' (\mathbf{M} \Sigma \mathbf{M}')^{-1} \mathbf{M} \hat{\mu}$ has a central chi-square distribution with degrees of freedom $L - 2$, the rank of $\mathbf{M}$. Because $\hat{\Sigma}$ is a consistent estimator of Σ , T defined in Eq. 9 has an asymptotic chi-square distribution by Slutsky Lemma.

Note that the above result can also be found in Ref. [8] It should be noted that for testing dose proportionality in Eq. 3, the T statistic in Eq. 9 has degrees of freedom $L - 1$ instead of $L - 2$.

SAMPLE SIZE CALCULATION

Sample size calculation can be obtained based on a pre-study power analysis for achieving a desired power of $1 - \beta$ for testing Eq. 2 under model 1. For simplicity, we assume that $n_k \equiv n$; that is, there are equal numbers of patients in each dose sequence (Figs.1–3). Under assumption that $n_k \equiv n$, define

$$\lambda = n^{-1} \mu \mathbf{M}' (\mathbf{M} \Sigma \mathbf{M}')^{-1} \mathbf{M} \mu \quad (10)$$

which is independent of n . As a result, formulas for sample size calculation based on a prestudy power analysis can be derived.^[8]

Theorem B. Under the assumption that $n_k \equiv n$, to achieve a desired power of $1 - \beta$ for testing Eq. 2, the sample size n satisfies the following equation

$$(L - 2) + n\lambda = \chi_{L-2, \alpha}^2 + z_\beta \sqrt{2(L - 2) + 4n\lambda} \quad (11)$$

Fig. 1 Individual dose response curves for sequence I

Fig. 2 Individual dose response curves for sequence II

or, approximately

$$n = 4 z_\beta^2 / \lambda$$

Proof: As indicated in Ref. [9] when n is large, the noncentral chi-square distribution can be approximated by a normal distribution as follows:

$$\chi_d^2(\lambda) = N(d + \lambda, 2(d + 2\lambda)) + O_p(\lambda^{-1/2}) \quad (12)$$

Then, under a fixed alternative in Eq. 5, we have

$$P(\chi_{L-2}^2(n\lambda) > \chi_{L-2, \alpha}^2) = 1 - \beta$$

Fig. 3 Individual dose response curves for sequence III

By Eq. 12, the above equation is asymptotically equivalent to

$$\frac{\chi^2_{L-2,\alpha} - (L-2+n\lambda)}{\sqrt{2(L-2)+4n\lambda}} = -z_\beta$$

hence Eq. 11. Let $n \rightarrow \infty$, we get $n = 4z_\beta^2/\lambda$.

TEST FOR DEPARTURE FROM LINEARITY

As pointed out by Chow and Liu^[4] and Law,^[10] measuring departure from dose linearity is also of clinical importance. Law^[10] briefly described a way to test the departure from dose proportionality/linearity based on the parametric regression model. However, no analysis of variance (ANOVA)-based tests are available for testing departure from dose linearity. Following Cheng et al.,^[8] it can be seen that when $n_k \equiv n$, λ given in Eq. 10 is a measure of departure from dose linearity. In fact, $\lambda = 0$ corresponds to the dose linearity and a large value of λ indicates a serious departure from dose linearity. The hypotheses for testing departure from dose linearity can then be written as follows.

$$H_0: \lambda \geq \lambda_0 \text{ vs. } H_1: \lambda < \lambda_0 \quad (13)$$

where λ_0 is a prespecified critical relevant limit. An asymptotically valid test for testing Eq. 13 can be derived based on the T statistic given in Theorem A.

Theorem C. Assume $n_k \equiv n$. For testing Eq. 13, an asymptotic size α test rejected H_0 if and only if

$$T < \chi^2_{L-2,1-\alpha}(n\lambda_0)$$

where T is given in Eq. 9 and $\chi^2_{m,\alpha}(\theta)$ is the $(1 - \alpha)$ th percentile of a noncentral chi-square random variable with noncentrality parameter θ and degrees of freedom m .

Proof: The result follows from the fact that $\chi^2_{L-2}(n\lambda)$ is stochastically decreasing with respect to its noncentrality parameter $n\lambda$.

Note that more details can be found in Ref. [8].

AN EXAMPLE

To illustrate the proposed testing procedures for assessment of dose proportionality/linearity and departure from linearity, we consider the following example.

Example. A dose proportionality study was conducted on 18 subjects to evaluate dose proportionality or linearity of AUC between the dose range of 60 and 480 mg of a pharmaceutical compound. The study design is a 3×3 incomplete crossover design with 4 dose levels, 3 dose sequences, and 3 dosing periods. Subjects were randomly assigned to one of the 3 sequences, and each subject has AUC responses at 3 dosing periods. The AUC data are given in Table 1. The plots of individual dose response curves for the 3 dose sequences are given in Figs. 1–3. From the plots, we see that the dose curve is not a straight line. Based on the above AUC data, the estimated quantities are

$$\hat{\mu} = (190.57, 459.7, 1297.75, 3400.98),$$

Table 1 AUC Data

Sequence	Subject	Dose levels (mg)			
		60	120	240	480

3	17	293.35	351.50	1569.30	

and

$$\hat{\sigma}_s^2 = 5.12, \quad \hat{\sigma}_e^2 = 0.69, \quad T = 7.74.$$

Since $T = 7.74 > \chi_{2,0.05}^2 = 5.99$, we reject the null hypothesis that the dose curve is linear. When the dose linearity hypothesis is rejected, a test for departure from linearity may be of interest. If we choose $\lambda_0 = 3.5$ in Eq. (13), then $T = 7.74 < \chi_{2,0.95}^2(21) = 9.44$. Therefore the null hypothesis in Eq. (13) is rejected and we conclude that the dose curves are not seriously different from a straight line under the chosen departure upper limit $\lambda_0 = 3.5$. It should be quickly noted that, in general, λ_0 should be chosen by authority group(s) based on the nature and particular purpose of the study.

DISCUSSION

In model 1, we assume that the standard deviation of the dose-response Y_{ijk} are proportional to the dose level X_{jk} . In practice, a logarithm transformation is usually suggested to achieve the constant variance. However, under model 1, the dose linearity means μ_{jk} follows a straight line. Therefore it may not be a good idea to consider a transformation of Y_{ijk} as the transformation will destroy the linearity of μ_{jk} .

The slope approach is essentially an ANOVA-based approach, which does not model the underlying dose curve as regression-based approaches do. Therefore the result for testing Eq. 2 need to be interpreted with caution. When H_0 in Eq. 2 is rejected, it can be concluded that the dose curve is not linear; while if H_0 is not rejected, to conclude that the dose curve is linear, some additional assumptions about the dose curve (e.g., that the dose curve is convex within the dose range under study) are generally understood.

As the dose linearity formulation in this entry is based on the adjacent slopes θ_l , it is also referred to as an adjacent slope approach, which is a special case of the slope approach first introduced by Chow and Liu.^[4] It should be noted that many other types of slopes could be considered. For example, we may define

$$\psi_l = \frac{\mu_{l+1} - \mu_l}{D_{l+1} - D_l} \text{ for } l = 1, \dots, L-1$$

which are the slopes with respect to the initial dose level D_1 . Thus the dose linearity test can be formulated as

$$H_0 : \psi_1 = \dots = \psi_{L-1} \text{ vs. } H_1 : H_0 \text{ is not true}$$

while the dose proportionality test can be formulated as

$$H_0 : \frac{\mu_1}{D_1} = \dots = \frac{\mu_L}{D_L} \text{ vs. } H_1 : H_0 \text{ is not true}$$

This approach is known as a baseline slope approach. The comparison of the baseline slope approach with the adjacent slope approach can be found in Ref. [11].

Abstract

This entry outlines models and methods for spatio-temporal analyses of spatially aggregated area rates, a topic of substantial development in recent years and summarizes several different processes of this modeling technique.

INTRODUCTION

Spatio-temporal models and related methods of inference have seen considerable development over the past decade primarily due to developments in statistical methodology for modeling spatial data and Bayesian computational methods, as well as accessibility of geographical information systems and mapping techniques. While there is a large body of work in the broad area of spatio-temporal models, this entry outlines models and methods for spatio-temporal analyses of spatially aggregated area rates, a topic of substantial development in recent years. A brief summary is also given of the models for spatial Gaussian processes, point pattern processes, and latent processes (reflecting hidden structure), respectively. The methods discussed herein have seen applications in disease epidemiology,^[1] disease surveillance and prevention,^[2,3] health outcomes studies,^[4,5] and environmental health research.^[1,4]

The broad focus of the spatial analysis of disease incidence, mortality, or health outcome rates is on visually describing the spatial distribution of small-area rates over space and time. The goal of such analyses is to produce smoothed maps for identifying spatial and temporal risk trends and to suggest factors that may be linked to various diseases or health outcomes for further epidemiological investigation or health outcome study. Often discussed under the subject title of “disease mapping,” the methodology has been developed to analyze spatially aggregated data, typically in the form of counts for the response, Y_{jt} , $j = 1, \dots, J$, $t = 1, \dots, T$, which represent the number of cases/events for each of the J subregions that constitute the region under study, with the data being collected over a consecutive set of time intervals such as months or years indexed by t . Also available is a set of counts N_{jt} , $j = 1, \dots, J$, $t = 1, \dots, T$, representing the “at-risk” population for the j th subregion in time period t . Age effects, and fixed or time-varying

covariates can also be incorporated into an analysis. For example, the methodology can be used to study geographical or regional variation in small-area prevalence rates of a drug prescription among a general population of a particular region under study, or differences in regional variation in utilization rates of a specific medication between males and females in a set of subregions.

Statistical models and methods for spatio-temporal analyses remain a relatively new arena of development. Some useful references in this area are Bernardinelli et al.,^[6] Waller et al.,^[7] Xia and Carlin,^[8] Knorr-Held and Besag,^[9] Sun et al.,^[10] Pickle,^[11] MacNab and Dean.^[12] Spatio-temporal models for spatially referenced point processes are common in environmental epidemiology and disease surveillance.^[13] Extensive treatment of models and methods for spatial data can be found in books by Cressie^[14] and Lawson et al.^[4] Edge effects in mapping studies are also discussed by Cressie.^[14] Wakefield and Morris^[15] discuss problems caused by aggregation and inaccuracies due to data collection, with specific reference to how these potentially lead to ecological bias and confounding.

SPATIO-TEMPORAL MODELS FOR AREA-AGGREGATED RATES

Spatial Models with Random Effects

Consider a common spatial model that involves a response $Y = (Y_1, \dots, Y_J)$ of independent Poisson random variables, corresponding to J local regions given a set of small-area random effects $\alpha = (\alpha_1, \dots, \alpha_J)$ and the “at-risk” population N_j , $j = 1, \dots, J$ for a particular time period considered (e.g., 1 or 5 years). The small-area random effects represent small-area relative risks which are generally of prime interest in these studies. Using a logarithmic link function in a generalized

linear mixed model framework, the conditional Poisson mean $\mu^\alpha = E(Y|\alpha)$ can be expressed as:

$$\log(\mu^\alpha) = X\beta + \alpha + \text{offset} \quad (1)$$

where X represents the design matrix and β the regression coefficients of fixed effects. The spatial random effects α reflect extra components of variability associated with the subregions under study, for example, variability arising from unobserved subregion covariates or latent effects. In a Poisson model, the offset represents a measure of exposure; here it is the logarithm of the population size. It is usual to account for age and gender in mapping studies, and model (1) can be extended in this manner.^[3,8] When the disease or mortality counts Y are aggregated over age and gender, an expected count is computed for each small area, usually based on the age- and sex-specific “at-risk” population sizes and standard rates for each age–sex stratum. This expected count is then used as the offset, and the relative risks α reflect a spatial comparison between observed and expected counts.^[1,4] When rates are not rare, the binomial mixed model is preferable.^[16]

A variety of distributional forms for the random effects have been proposed and discussed in the disease mapping literature. A simple spatial model proposed by Besag, York, and Mollié^[17] is the intrinsic Gaussian autoregressive (IGA) model, which accounts for what is termed locally structured spatial variation. Assuming a multivariate normal distribution for α , the IGA model describes the conditional distribution of α_j , given all other random effects, $[\alpha_i | \alpha_i, i \neq j]$, as depending only on those spatial random effects in a small local neighborhood of the j th subregion:

$$\alpha_j | \{\alpha_i, i \neq j\} \sim N(\bar{\alpha}_{(j)}, \sigma_\alpha^2 / \delta_j) \quad (2)$$

where $\bar{\alpha}_{(j)}$ represents the mean of the random effects corresponding to the subregions that belong to the “neighborhood” of the j th area and δ_j is the number of areas forming this neighborhood. The conditional variance in (2), $V(\alpha_j | \{\alpha_i, i \neq j\})$, is inversely proportional to the number of neighbors of the j th area. Neighborhoods may be defined in various ways, depending on the context of the analysis, but one common definition is simply the set of areas that border the j th area. Unconditionally, the IGA model becomes

$$\alpha \sim N(0, \Sigma) \quad (3)$$

where the generalized inverse of Σ is $\Sigma^{-1} = Q/\sigma_\alpha^2$; Q is a square matrix of dimension J determined by the neighborhood structure of the regions. Under the given specification (2) for example, the neighborhood matrix Q has j th diagonal element δ_j , and the off-diagonal elements Q_{jk} , $j \neq k$, equal to -1 if the subregions j and k are neighbors, and 0 otherwise.

More general formulations define the mean $E(\alpha_j | \{\alpha_i, i \neq j\})$ as a weighted average of all the other area-specific effects. To give more influence to “local” areas, the weights may vary with distance from area j :

$$\alpha_j | \{\alpha_i, i \neq j\} \sim N\left(\frac{\sum_i W_{ij} \alpha_i}{\sum_i W_{ij}}, \frac{\sigma_\alpha^2}{\sum_i W_{ij}}\right) \quad (4)$$

where $\{W_{ij}, i = 1, \dots, J, j = 1, \dots, J, i \neq j\}$ are user-specified weights linking subregions i and j .^[15,18]

As with any generalized linear mixed model (GLMM), various components of variability may also be included. A common extension to the IGA model uses:

$$\Sigma = \sigma_\alpha^2 Q^{-1} + \sigma_u^2 I_J \quad (5)$$

where I_J is an identity matrix of dimension J ; σ_α^2 models spatially structured variation as previously, while the additional component σ_u^2 incorporates unstructured variation.^[17] Leroux, Lei and Breslow^[19] offer an alternative formulation to (5), which builds upon the idea of conditional modeling, where it is the inverse of the variance that is modeled as having these two components, so that conditional distributions of random effects are as easily interpreted as in the IGA model. In this case

$$\Sigma = \sigma^2 D^{-1}, \quad D = \lambda Q + (1 - \lambda) I_J \quad (6)$$

Here, σ^2 is the dispersion parameter and λ , $1 \geq \lambda \geq 0$, measures the spatial autocorrelation. It should be noted that model specification (6) reduces to a Gaussian independence/exchange model if $\lambda = 0$ or to the IGA model if $\lambda = 1$. The Gaussian independence assumption, on one hand, models spatially “unstructured” variation and leads to “global” smoothing, and the IGA model, on the other hand, assumes purely neighborhood (spatially) “structured” effects and results in maximum “local smoothing.” By allowing λ to vary between 0 and 1, the conditional autoregressive (CAR) specification (6) facilitates spatial smoothing in accordance with the extent to which areas of close spatial proximity have similar underlying disease rates.^[5,16] MacNab^[5] presents a comparison of random spatial effect models under assumptions (5) and (6).

Spatio-Temporal Models

Let j denote the indices for area units, or area–age units, if age effects are included. General spatio-temporal models with Poisson intensity $\mu(j, t)$, conditional on random effects $\mathbf{b}$, can be expressed as:

$$\mu(j, t) = \rho \lambda_0(j, t) \lambda_j(j; \boldsymbol{\beta}^{(j)}, \mathbf{b}^{(j)}) \lambda_{j,t}(j, t; \boldsymbol{\beta}^{(j,t)}, \mathbf{b}^{(j,t)}), \quad (7)$$

where ρ represents the offset, $\lambda_0(j, t)$ the area–time (or area–age–time or age–time) conditional intensity of the “at-risk” population, $\lambda_j(j; \beta^{(j)}, b^{(j)})$ the spatial variability attributable to time-constant covariates (with regression coefficients $\beta^{(j)}$) and residual spatial effects ($b^{(j)}$), and, assuming a log-linear form for $\lambda_{j,t}$ to aid in exposition,

$$\lambda_{j,t}(j, t; \beta^{(j,t)}, b^{(j,t)}) = \exp[X(j, t)\beta^{(j,t)} + \gamma(j, t)] \quad (8)$$

with $X(j, t)$ denoting time–varying covariates and $\gamma(j, t)$ representing area–time (or area–age–time) residual variation, thus allowing for area–time interactions. Corresponding models for the binomial likelihood can be handled.^[20]

Specific spatio-temporal random effect Poisson models for the analysis of small-area disease rates have been proposed and discussed by Waller et al.,^[7] Sun et al.,^[10] MacNab and Dean,^[12] among others. In particular, the aforementioned authors extend spatial autoregressive models to include temporal components. In Ref. [7], the index j refers to area–stratum units, where the strata may be gender and race, for example. The area–stratum covariates are fixed over time, and the stratum covariates are fixed over area. This form would assume that sex and race effects are not affected by area and time. The logarithm of λ_j in (7) is written as a sum: $X_{j1}\beta_1 + X_{j2}\beta_2$, where X_{j1} is the design matrix for the stratum effects, including interactions, for example, race–gender interactions, and X_{j2} is the design matrix for the fixed area effects. The space–time interaction model defines the logarithm of $\lambda_{j,t}$ as including both spatial and unstructured random effects that vary over time. For example, the spatial random effects for given t may follow an IGA model. Simpler models are also considered in an analysis of Ohio lung cancer including one with $\lambda_{j,t}$ being a linear function of t and without area or temporal random effects. Other models mentioned in the paper include the temporal effect in an autoregressive AR(1) structure. Xia and Carlin^[8] extend Waller et al.^[7] to allow for errors in covariates.

In Ref. [10] where the index j refers to area–age units, temporal trends are modeled as linear functions of t . The logarithm of λ_j includes fixed age and random spatial effects, the latter following a modification of the IGA model. The spatio-temporal component permits a different trend effect over age groups, i.e., the fixed coefficients of the linear temporal effect differ over age groups. There are also random area coefficients of the linear temporal effect permitting random area trends over time.

Nonlinear forms for temporal trends are accommodated in MacNab and Dean^[12] via spline smoothing. Splines^[21–23] permit a broad class of arbitrary smooth functions of time. The logarithm of λ_0 includes a cubic spline that models the trend over the whole region considered, or, if age-group effects are included, a two-dimensional fixed spline to represent the overall trend over the age–time surface. Random temporal spline effects are included in $\lambda_{j,t}$, permitting the

random area relative risks to vary over time in a nonlinear fashion. Simpler spatio-temporal effects are also considered, for example, having the random area relative risks vary linearly over time as in the other spatio-temporal models above. Large positive and negative values of these linear area trend terms then identify areas whose rates are increasing the fastest, or decreasing the slowest with respect to the overall trend over the entire area.

ESTIMATION

Empirical Bayes Methods

The above mentioned models can be readily represented by the following GLMM framework:^[24]

$$g(\mu^b) = Xa + Zb + \text{offset} \quad (9)$$

where $\mu^b = E(Y|b)a$, and b indicate the fixed and random effects, and X and Z the corresponding design matrices. Estimation can be implemented using empirical Bayes techniques that make use of likelihood-based procedures, such as maximum likelihood estimation (MLE) [or restricted maximum likelihood estimation (RMLE)]^[25] to estimate hyperparameters, and a “plug-in approximation” to the posterior inference of the random effects.

Full maximum likelihood estimation for random effects Poisson or binomial models often requires numerical integrations that are intractable. For computational simplicity, the use of penalized quasilielihood (PQL), a second order Laplace approximation to the integrated quasilielihood function, may be used. The PQL method was popularized by Breslow and Clayton^[24] for inference within the GLMM framework; the algorithm has been used in empirical Bayes disease mapping estimation for Poisson count data.^[12,19] Specifically, by introducing a modified working response variable:

$$Y^* = \log y + (y - \mu^b)/\mu^b - \log N \quad (10)$$

PQL fitting proceeds by considering Y^* to be derived from an associated normal theory mixed model.^[24]

The PQL algorithm typically yields consistent and nearly unbiased point estimates of the relative risks under Poisson likelihood. For nonrare outcomes and random effects binomial models, the second order Laplace approximation to the corresponding integrated quasilielihood function may result in considerable bias in the PQL estimators. In such cases, a higher-order Laplace approximation to the corresponding integrated quasilielihood function might be explored for bias corrections. Potential alternatives for the GLMM inference also include double PQL^[26] and the so-called expectation–maximization (EM) algorithm.^[27,28]

Full Bayesian Methods

The disease mapping literature also presents numerous applications of Markov chain Monte Carlo (MCMC) methods for full Bayesian (FB) estimation of relative risks. Unlike the naive empirical Bayes' methods, a fully Bayesian approach permits inference for relative risks based on estimated posterior distributions where the uncertainty associated with the estimates is properly characterized.^[29] Fully Bayesian disease mapping inference is commonly implemented via Gibbs and adaptive rejection sampling. The methods, however, may suffer from slow mixing when high posterior correlations occur, or when a large number of geographical areas are investigated and the data are sparse.^[4,29] More recently, alternative MCMC algorithms for Bayesian inference of relative risks have been explored.^[16,30]

OTHER SPATIO-TEMPORAL MODELS

Models for Spatial Gaussian Processes

The basic spatial models for continuous data assume normality of the spatial responses. Let $Z(s_i) = Z_i$ and μ_i represent the responses and their means at location s_i . The conditional specification of the model assumes that conditional on $\{Z_j, j \neq i\}$, the distribution of $Z_i, i = 1, \dots, n$ is normal with mean of the form

$$E\{Z_i | (Z_j, j \neq i)\} = \mu_i + \sum_{j=1}^n c_{ij}(Z_j - \mu_j)$$

and variance

$$\text{Var}\{Z_i | (Z_j, j \neq i)\} = \sigma^2$$

Here, $c_{ii} = 0$, $c_{ij} = c_{ji}$, and the mean usually depends only on responses in a small neighborhood of site s_i with $c_{ij} = 0$ unless sites s_i and s_j are neighbors. When $c_{ij} > 0$, there is positive interaction between sites; $c_{ij} < 0$ implies negative interactions. If a regression form for the mean is assumed, so

$$\mu_i = \beta_0 + \beta_1 x_1(s_i) + \beta_2 x_2(s_i) + \dots + \beta_p x_p(s_i)$$

where $x_j(s_i)$ is the value of the j th explanatory variable at site i , then the joint distribution of the responses is of the multivariate regression form:

$$Z \sim N(X\beta, \sigma^2(I - C)^{-1})$$

where X is

$$\begin{pmatrix} 1 & x_1(s_1) & \dots & x_p(s_1) \\ & & \ddots & \\ 1 & x_1(s_n) & \dots & x_p(s_n) \end{pmatrix}$$

I is the identity matrix, and C is the matrix with ij th element c_{ij} . Simple models define $c_{ij} = 1$ if i and j are neighbors, and 0 otherwise. Other models permit c_{ij} to depend on a measure of distance between s_i and s_j and vary the structure of the conditional variance. If the sites do not occur as a regular lattice then a conditional variance that takes into account the cardinality of the neighborhood may be more appropriate. Another class of models for continuous data uses simultaneous (instead of conditional) autoregressive models. Under the simultaneous autoregressive model (known as the SAR model^[14]),

$$[Z(s_i) - \mu_i] - \sum_{j=1}^n b_{ij}[Z(s_j) - \mu_j] = \epsilon(s_i)$$

where $\epsilon(s_1), \dots, \epsilon(s_n)$ are independent normal variates with zero mean and variance σ^2 . The coefficients b_{ij} must satisfy: $b_{ii} = 0$, $b_{ij} = 0$ unless sites s_i and s_j are neighbors. The joint distribution of the responses becomes multivariate normal with mean μ and variance $\sigma^2(I - B)^{-1}(I - B')^{-1}$ (B' indicates transpose of B) where I is the identity matrix; B has elements b_{ij} . Analogs to time-series moving average models are also available in the spatial context. Extensions to consider spatio-temporal analysis follow similarly as for count data. For example, autoregressive models for the temporal dimension could be explored or models incorporating splines could be used.

Relatively well-developed models for spatial processes and continuous responses have been used in the analyses of geostatistical data.^[14] The models and methods have been applied to public health research such as the analysis of small-area sudden-infant death syndrome data.^[14,31]

Models for Point Pattern Processes

Models for point pattern processes are developed for case-event data, with risk intensity of cases and the corresponding locations of events being of particular interest.^[4,13] Investigation of disease risks through point process modeling requires cases and event specific data at the individual level, permitting the assessment of spatial risk patterns and risk clustering. Spatio-temporal models of case-event data remain relatively unexplored. Recently, Diggle et al.^[13] discussed and explored spatio-temporal point process models for spatial disease surveillance.

Discrete Mixture Models

Discrete mixture spatial models^[32-34] are also common for mapping small-area rare rates and for cluster analysis. This nonparametric mixture model approach assumes that the region-specific random effects have a discrete probability distribution taking k values $R_1, \dots, R_k$ with probabilities $p_1, \dots, p_k$, respectively. The mixture model represents k latent components or clusters in relative risks containing a

proportion p_j from the population. If k is fixed, estimation via the EM algorithm is straightforward.^[27,28] Flexibility in the number of clusters permits the isolation of extreme relative risks and therefore enables the assessment of whether a region is in a high-risk cluster.^[33] Spatio-temporal mixture models for mapping disease risks over space and time are explored and discussed in Böhning, Schlattmann, and Lindsay.^[34] Green and Richardson^[35] have recently proposed the use of hidden Markov random field models for the analysis of rare disease rates so that spatial correlation in the probabilities of belonging to various clusters is achievable.

AN EXAMPLE

We present here an illustrative spatio-temporal analysis of injury hospitalization rates among children of age 0–19 in British Columbia (BC), Canada. Specifically, we present here an analysis of child injuries due to accident falls. The data consist of annual incidence cases y_{ijt} of accident falls and the midyear “at-risk” population estimates n_{ijt} for young girls of age 0–4, 5–14, and 15–19 ($i = 1, 2, 3$) in 20 health regions in British Columbia ($j = 1, \dots, 20$), and from 1987 to 1996 ($t = 1987–1996$), respectively. Conditional on random effects $\mathbf{b}$, we assume a Poisson likelihood for the observations y_{ijt} with mean:^[3,12]

$$\mu_{ijt} | \mathbf{b} = n_{ijt} m \exp[S_0(t) + a_{0i} + a_{it}] \exp(\gamma_j) \times \exp(RS_j(t)) \quad (11)$$

or via log-link we assume:

$$\log(\mu_{ijt} | \mathbf{b}) = \log(n_{ijt}) + \log(m) + S_0(t) + a_{0i} + a_{it} + \gamma_j + RS_j(t) \quad (12)$$

where $\log(n_{ijt})$ is the offset; m represents the mean rate over all local regions at the midpoint of the time period considered (when t is centered, as is the case in the application); $\{a_{0i}\}$ and $\{a_{it}\}$ represent fixed age effects; $S_0(t)$ is a single spline representing the BC (“global”) trend and $\{RS_j(t)\}$ a family of random splines representing regional (“local”) trends relative to the “global” spline; γ_j is the random area effect and $\gamma = (\gamma_1, \dots, \gamma_{20}) \sim N(\mathbf{0}, \Sigma_\gamma)$. Specifically, model (11) corresponds to the broad spatio-temporal model framework in Eq. (7) such that λ_0 , the fixed age-time component in (7), is $m \exp[S_0(t) + a_{0i} + a_{it}]$; λ_j , the random spatial effects, are here $\exp(\gamma_j)$; and $\lambda_{j,t}$, the random spatio-temporal interaction, is $\exp(RS_j(t))$.

In this example, regression B-splines with one inner knot are used for the fitting of the fixed and random temporal effects $S_0(t)$ and $RS_j(t)$; the estimated model appears to produce adequate prediction of the rates and ratios using B-splines of order 2. Thus, in this example, we assume the following specifications for the spline terms:^[3,12]

$$S_0(t) = \sum_{k=1}^3 a_{0k} B_k(t) \quad (13)$$

and

$$RS_j(t) = \sum_{k=1}^3 \beta_{jk} B_k(t) \quad (14)$$

where $\{B_1(t), B_2(t), B_3(t)\}$ denote corresponding B-spline basis functions (without the intercept term) evaluated at time t (t is centered); $\beta_k = (\beta_{1k}, \dots, \beta_{jk})^T$ are random spline coefficients with respect to $B_k(t)$, $\beta_k \sim N(\mathbf{0}, \Sigma_k)$, $k = 1, 2, 3$.

The PQL analysis is presented here, assuming that the conditional expectation of y_{ijt} given the random effects follows (12–14), with variance–covariance matrix:

$$\Sigma_b = \begin{pmatrix} \Sigma_\gamma & \rho I_{20} & \rho I_{20} & \rho I_{20} \\ \rho I_{20} & \Sigma_1 & 0 & 0 \\ \rho I_{20} & 0 & \Sigma_2 & 0 \\ \rho I_{20} & 0 & 0 & \Sigma_3 \end{pmatrix} \quad (15)$$

where I_{20} is a 20×20 identity matrix. The variance–covariance matrices Σ_γ and Σ_{β_k} may be assumed to follow one of the CAR specifications given by Eqs. (4)–(6). Preliminary analyses indicated that the spatial correlations, among spatial random effects ensemble γ , as well as β_k , $k = 1, 2, 3$ are small and negligible. Here, we present the analysis assuming $\Sigma_\gamma = \sigma_\gamma^2 I_{20}$, $\Sigma_k = \sigma_{\beta_k}^2 I_{20}$, $k = 1, 2, 3$, $\text{Corr}(\gamma, \beta_k) = \rho$, $k = 1, 2, 3$, $\text{Corr}(\beta_r, \beta_k) = 0$, $k \neq r$. Note that the inclusion of age effects allows one to predict age- and region-specific rate and ratio trends as well as age-adjusted region-specific ratio estimates.

The data suggest some evidence of over dispersion; Table 1 lists the estimates of the variance components and the model coefficients. Fig. 1 plots provincial rate spline estimates by age group, showing mild curvature in provincial rates. The injury rates are considerably lower for girls in their mid-teens to mid-twenties while young girls between age 5 and 14 appear to be more likely to have such injuries. Fig. 2 displays age-adjusted injury ratio estimates for each of the 20 health regions, indicating regions of high injury risks: North Okanagan, Thompson, Coast Garibaldi, Upper Island/Central Coast, and Northern Interior, and those of low risks: Vancouver, Burnaby, North Shore, and Richmond. Increasing trends in injury risks were observed in health regions North Okanagan, Coast Garibaldi, Upper-Island/Central Coast, and Capital. Rate and ratio estimates can also be examined by health region by age group. To conserve space, Fig. 3 plots the health region rate splines for young girls of age 5–14, where temporal smoothing predicts moderate curvature for most of the health regions. Clearly,

Table 1 Spatio-Temporal Model Fit to BC Child Injury Hospitalization Rates, Accident Falls, Girls Age 0–19, 1987–1996

Parameter	Estimate	Std. error
$\log m$	−4.163	0.04613

for young girls of age 5–14, injuries caused by accidental falls declined in all 20 regions, and similar trends, not shown here, are observed for young girls of other age groups. Fig. 4 maps age-adjusted injury ratios for health regions from 1987 to 1996; a change in spatial pattern

is observed, with high injury risk clusters shifting from northwest towards the southcentral.

CONCLUSIONS

This entry gives a cursory review of spatial and spatio-temporal models and related methods of inference. A recent monograph by Banerjee, Carlin, and Gelfand^[36] presents a current account on spatial and spatio-temporal models and related issues, methods, and applications. The book also presents recent developments of spatial and spatio-temporal frailty models for analysis of survival (or time-to-event) data. Implementations of spatio-temporal modeling remain considerably challenging primarily due to the model and the computational complexity, as related analyses essentially aim to explore and tackle spatial correlation, temporal correlation, and spatial–temporal interaction within a unified modeling framework. Currently available software packages do not readily facilitate complex spatio-temporal modeling. Most applications to date involve extensive computer programming and coding is often done on a case-to-case basis. Recent developments of statistical and computational software such as WinBUGS (<http://www.mrc-bsu.cam.ac.uk/bugs>), Splus (<http://www.insightful.com>), and others, as well as geographical information system (GIS) software, such as ArcView and ArcGIS (<http://www.esri.com>), provide the potential for more accessible software-facilitated spatio-temporal analysis procedures in the near future.

Specifications

John R. Murphy

Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

Abstract

Specifications on the physical and chemical attributes of drug substances and drug products are the quality standards that provide the patient assurance that the drug will perform its intended purpose without unexpected side effects. This entry gives a brief overview of how these specifications are determined.

INTRODUCTION

In the pharmaceutical industry, “specifications” usually mean the same thing as “specification limits,” which refer to numerical tolerances within which the measured result for a quality attribute of a dosage form should fall. Specifications may also refer to more general and/or complex criteria, which can sometimes be found in a compendium such as the United States Pharmacopeia and National Formulary (USP/NF).^[1] An example of specification limits that are numerical tolerances might be where the purity of a drug substance must be no less than 97.0% and no more than 103.0%. An example of specifications based on more general criteria might be where a solid oral dosage form must meet the USP dissolution criteria using a Q of 75% at 45 minutes.

OVERVIEW

Specifications on the physical and chemical attributes of drug substances and drug products are the quality standards that provide the patient assurance that the drug will perform its intended purpose without unexpected side effects. In that sense, specifications may be thought of as defining the numerical tolerances or other criteria that make the drug safe, effective, and fit for use. Ideally, specification limits based on those considerations could be established, and the manufacturing process would be capable of providing units falling well within such bounds. In practice, however, many times the allowable limits based on safety, efficacy, or fitness for use seem too wide, stemming from a belief that narrow or tight specifications mean a higher-quality product. The net result is that the determination of specification limits is sometimes based almost entirely on judgments about manufacturing capability.

Because specifications are a legal commitment with regulatory authorities, their determination is an important undertaking, and the process of getting to agreed-upon

specifications is sometimes difficult. Part of the problem is the complexity of the measurement process, which can often comprise a significant amount of the variation in the measured results. As a result, many specifications cannot be set without tying them to the analytical methods that produce the result. Another feature of drug substances and drug products is that degradation be factored into the process of setting specifications. Stability estimation can present a special problem because the effect (change over time) is often small relative to the variation in the manufacturing and the measurement processes. Given these facts, it seems evident that determining rational specifications requires the use of statistical methods to estimate and account for all the variation that may be present.

Specifications mean different things to different people, and part of the reason for this is a failure to recognize the difference between several types of limits that are derived to meet different purposes.^[2] The type of specification limits that most often come to mind are “expiry specifications” or “regulatory specifications,” which are the limits a product must meet throughout its shelf life and which are documented in a regulatory submission or compendial monograph. The failure of units in commercial distribution to comply with expiry specifications is a serious matter that can result in regulatory censure and/or expensive and time-consuming product recall. In order to minimize the probability of out-of-specification results, manufacturers utilize “release specifications” or “acceptance limits,” which are applied at the time of product release. In the United States, release limits are still considered by the FDA to be mostly a matter of internal company policy, while in Europe the release limits must be formally registered in the regulatory dossier. The third type of limits are what may be informally regarded as “statistical control limits,” which reflect the capability of a manufacturing process in a state of statistical control and serve to alert us to unusual results that are likely to be the consequence of special causes.

One primary reason for disagreement about how wide or narrow expiry specifications should be is a misunderstanding

and lack of agreement about the function and the relative location of these three types of limits. The purpose of release limits is to prevent noncomplying products from reaching the marketplace, and they are best determined using statistical methods that take into account the sampling and measurement variation and the change in the product attribute over time. Ideally, they are set from the expiry limits inward such that if the batch result falls within the release limits, there is a specified level of confidence that future measurements will fall within the expiry limits. In and of themselves, release limits do not have any relation to the capability of the process to produce results that will fall within them. Statistical control limits, on the other hand, are related to the capability of the process, and when the release limits are at least as wide as the statistical control limits, the process will be capable of producing results that have a high probability of falling within the release limits. Unfortunately, sufficient data firmly to establish control limits and release limits may not be available at the point in time in the development process when the limits need to be set; it is therefore imperative that regulatory bodies worldwide recognize the need for expiry limits and release limits to be wider at first approval. There can be an expectation that specification limits will be appropriately tightened as more supporting process data becomes available.

Currently, there is no international consensus on the approach to specification setting, but International Conference on Harmonization (ICH) document Q6A on specifications^[3] is a large step forward. This guideline provides common definitions, discusses justification of specifications, and gives a listing of the analytical properties that may be considered universal for drug substances and the various dosage forms of drug products. The use of

statistical methods is not specifically mentioned or encouraged in the document, but the necessity of establishing release specifications separate and different from expiry specifications is recognized.

CONCLUSION

In summary, specifications define the standards of identity, strength, quality, and purity of drug products. The patient derives assurance that the drug will perform its intended function from the knowledge that its physical and chemical properties have been tested and have been determined to comply with those standards. Good specifications are those that guarantee that the product will be safe and effective while at the same time providing sufficient latitude for the manufacturer to produce and release product that is highly probable to remain within specification throughout the shelf life. Such specifications are best developed with the aid of statistical methods.

Abstract

The summary receiver operating characteristic (SROC) curve has been recommended to represent the performance of a diagnostic test, based on data from a meta-analysis. This entry aims to detail the process of a meta-analysis of diagnostic test data and discuss issues with using the fixed-effect model.

Keywords: Area Under the Curve (AUC); Diagnostic test evaluation; Fixed effects; Hierarchical mixed effects; Meta-analysis; Sensitivity; Specificity; Summary receiver operating characteristic (SROC) curve.

INTRODUCTION

The summary receiver operating characteristic (SROC) curve has been recommended to represent the performance of a diagnostic test, based on data from a meta-analysis. Under a fixed-effect, logit-threshold model, the position of the SROC curve can be characterized in terms of the overall diagnostic odds ratio and the magnitude of inter-study heterogeneity. The Area Under the Curve (AUC) and an index Q^* are potentially useful summary measures. It is shown that AUC is maximized when the study odds ratios are homogeneous, and that it is quite robust to heterogeneity. An explicit upper bound is derived for AUC in the homogeneous situation, and a lower bound based on the limit case Q^* , defined by the point where sensitivity equals specificity: Q^* is invariant to heterogeneity. The standard error of AUC is derived for homogeneous studies, and is shown to be a reasonable approximation with heterogeneous studies. AUC and its standard error are easily computed in the homogeneous case, and avoid the need for numerical integration in the more general case. $SE(AUC)$ and $SE(Q^*)$ are numerically close, with $SE(Q^*)$ being larger if the odds ratio is very large. Motivation for the use of the AUC and Q^* measures as summaries of the SROC curve are discussed.

Multi-level mixed models are also described which provide a more general framework for SROC estimation that take account of within study sampling error for both sensitivity and specificity, and also include random study effects to take account of additional unexplained variability in test performance.

META-ANALYSIS OF DIAGNOSTIC TEST DATA

Systematic reviews of primary studies are becoming increasingly important for summarizing evidence about the accuracy of diagnostic tests. Guidelines for the conduct of such reviews^[1–4] include defining the objectives, retrieval of the relevant literature, data extraction, meta-analytic methods for obtaining summary estimates of test accuracy, and investigating reasons for variation in test accuracy across studies.

The receiver operating characteristic (ROC) curve is well established as a method of summarizing the performance of a diagnostic test within a single study.^[5–7] It indicates the relationship between the true positive rate (TPR) and the false positive rate (FPR) of the test, as the threshold used to distinguish disease cases from noncases varies. For instance, the threshold might be a defined level of serum cholesterol as a marker of cardiovascular disease, or a particular level of cellular abnormality as a marker of malignancy. The summary receiver operating characteristic (SROC) curve and the area under the curve (AUC) have been proposed as a way to describe diagnostic data in the context of a meta-analysis.^[1,2,4,8–11]

A schematic ROC curve is shown in Fig. 1. All of its data points come from a single study, and are defined by the results arising when one of several alternative thresholds (or cut points) on the test results is used to discriminate between disease cases and noncases. Liberal thresholds that give high values of TPR will tend to incorrectly label a relatively high fraction of the noncases as cases, so the false positive rate (FPR) will be high. Conversely, conservative

Fig. 1 Schematic ROC curve

thresholds yield incorrect labels for noncases rather infrequently, but at the cost of detecting a smaller fraction of the true cases; in this situation, the value of TPR and FPR are both relatively low. Thus one generally expects TPR and FPR to be positively associated. In the ROC space, points near the lower-left corner correspond to conservative thresholds (low TPR and low FPR values), and points near the upper-right corner correspond to liberal thresholds (high TPR and high FPR values).

In a single study, changing the threshold necessarily results in monotonic changes in TPR and FPR. Accordingly, the ROC curve can always be empirically represented, in its simplest form by connecting the data points as shown in Fig. 1. Alternatively, smoothed curves can also be fitted using a latent variable approach, based on a model that the case and noncase test values follow normal or logistic distributions.^[12–20]

In a meta-analysis, the units of analysis are separate studies. In the simplest case, each study contributes an estimate of TPR and FPR. The SROC curve represents the relationship between TPR and FPR across studies, recognizing they may have used different thresholds. In contrast to the ROC analysis, the set of (FPR, TPR) points does not necessarily yield a unique, monotonic curve. Several methods have been proposed for fitting an SROC curve;^[8,11,21,22] this paper will focus on the properties of the popular method developed by Moses et al.^[11] Alternative but more complex hierarchical models such as that proposed by Rutter and Gatsonis^[21,22] are also outlined and their potential advantages are discussed.

LOGIT-THRESHOLD FIXED EFFECT MODEL FOR SUMMARY RECEIVER OPERATING CHARACTERISTIC CURVE

The most popular method to obtain a smoothed fit of the SROC curve is to use the regression model proposed

by Moses et al.^[11] The dependent and independent variables are

$$D = \ln\left(\frac{\text{TPR}}{1 - \text{TPR}}\right) - \ln\left(\frac{\text{FPR}}{1 - \text{FPR}}\right) \quad (1)$$

and

$$S = \ln\left(\frac{\text{TPR}}{1 - \text{TPR}}\right) + \ln\left(\frac{\text{FPR}}{1 - \text{FPR}}\right) \quad (2)$$

respectively. D is equivalent to the diagnostic log odds ratio, $\ln(\text{OR})$, which conveys the test's accuracy in discriminating cases from noncases. S is a function of the diagnostic threshold in a study, with high values corresponding to liberal inclusion criteria for cases. $S = 0$ when $\text{TPR} = 1 - \text{FPR}$, i.e., on the antidiagonal from the top-left to bottom-right corners of the SROC space. The regression equation

$$D = a + bS \quad (3)$$

can be fitted by standard least squares methods, assuming that D is approximately normally distributed for a given value of S . Optionally, weights can be employed to reflect interstudy heterogeneity with respect to the sample variance of D , or a robust fitting procedure may also be used.^[11] The coefficient b in Eq. 3 represents the dependence of the test accuracy on threshold. If $b \approx 0$, then the studies will be referred to as *homogeneous*; they can then be summarized by an overall OR, noting that $a = \ln(\text{OR})$. If $b \neq 0$, then the studies are referred to as *heterogeneous* with respect to OR. In this case, a can be thought of as the value of $\ln(\text{OR})$ when $S = 0$.

This model assumes logistic distributions for the test values in the cases and noncases, but normal distributions may also constitute an adequate approximation. However, the model is generally fitted without directly appealing to the logistic distribution assumption. If the underlying test results actually have logistic distributions, then S for a given study can be expressed as a function of the cut point that gives rise to the sensitivity and specificity for that study.^[11] If the variances of the distributions of test results for the cases and noncases are equal, then the SROC is symmetric about the diagonal line where $\text{TPR} = 1 - \text{FPR}$. If the variances are unequal, the resulting SROC will be asymmetric. No assumptions are made about the distribution of S . Covariates may be added to the model to assess whether test accuracy varies systematically with other study-related factors.^[23,24]

If the estimate of test accuracy for each study is weighted by the inverse of its variance, one is assuming that sampling error is the only source of variability between studies. However, this assumption may be unrealistic, given that studies are likely to vary in a number of respects, including the spectrum of disease, conditions under which the test was administered, and

other study and patient characteristics that could affect test accuracy.^[25–27]

Although the parameters a and b are both fixed because they are assumed to be constant across studies, applying equal weights to studies (i.e., fitting an unweighted regression) has been empirically shown to give results that are consistent with assuming a random effect.^[9,11,21] This is because both the within- and between-study variances are taken into account, thereby giving relatively more weight to smaller studies, as would occur in a random effect model. Irwig et al.^[9] recommend the unweighted analysis, because weights based on sample variances may give too much emphasis to inaccurate studies, and hence give a biased SROC curve. Moses et al.^[11] also recommend the unweighted approach.

Once the regression has been fitted, one can reverse the transformations (Eqs. [1] and [2]) and hence deduce the relationship between TPR and FPR as

$$\text{TPR} = \frac{\exp\left(\frac{a}{1-b}\right)\left(\frac{\text{FPR}}{1-\text{FPR}}\right)^{(1+b)/(1-b)}}{1 + \exp\left(\frac{a}{1-b}\right)\left(\frac{\text{FPR}}{1-\text{FPR}}\right)^{(1+b)/(1-b)}} \quad (4)$$

Expression 4 gives TPR at any given value of FPR, and hence defines the entire SROC curve. While there may be interest in identifying particular points on the curve, it is also useful to have an overall summary measure of the curve's behavior. One appropriate measure is the Area Under the Curve (AUC), which can be calculated as

$$\text{AUC} = \int_0^1 \frac{\exp\left(\frac{a}{1-b}\right)\left(\frac{x}{1-x}\right)^{(1+b)/(1-b)}}{1 + \exp\left(\frac{a}{1-b}\right)\left(\frac{x}{1-x}\right)^{(1+b)/(1-b)}} dx \quad (5)$$

In general, AUC must be numerically obtained, because there is no closed form for expression 5.

Adoption of a summary index is helpful for succinct reporting of a given data set, especially when limited data preclude the reliable identification of particular points on the curve. The AUC measure is widely used in ROC analysis, where it can be interpreted as the probability that the test values for a random pair of diseased and nondiseased individuals would be correctly ranked; it also represents the (unweighted) average of TPR over all possible values of FPR.

The AUC is also a natural candidate summary for an SROC analysis. We will consider the alternative index Q^* , which will be defined as a point of indifference on the SROC curve, where the probabilities of an incorrect test result are equal for disease cases and noncases. The partial AUC has also been proposed as a summary measure, this being the area under some restricted portion of the curve corresponding to FPR values of clinical interest, or in which study data are located.

EMPIRICAL BEHAVIOR OF THE SUMMARY RECEIVER OPERATING CHARACTERISTIC CURVE

Fig. 2 shows a set of three symmetric SROC curves with $b = 0$, which occurs when the studies are homogeneous and thus exhibit no relationship between OR and threshold (S). The curves were obtained by numerical evaluation of Eq. 4 for $a = 1.5, 2$, and 3 , which correspond to $\text{OR} = 4.5, 7.4$, and 20.1 , respectively. As a increases, the SROC curve moves closer to its ideal position near the upper-left corner. If $a \rightarrow \infty$, then $\text{AUC} \rightarrow 1$, which would indicate a perfect test having 100% sensitivity and specificity, and no errors in distinguishing cases from noncases. In contrast, if $a \approx 0$ (or $\text{OR} \approx 1$), the curve lies close to the diagonal $\text{TPR} = \text{FPR}$ in the SROC space; then, $\text{AUC} = 1/2$ and the test performs no better than chance.

For completeness, we mention situations where $a < 0$. These correspond to $\text{OR} < 1$, when the test discriminates cases and noncases in the “wrong” direction, and *worse* than at random. As $\text{OR} \rightarrow 0$, $\text{AUC} \rightarrow 0$, and the curve lies close to the lower-right corner of the SROC space. Such situations are unlikely to occur in practice.

We now consider the case of heterogeneous studies under model 3, where diagnostic accuracy depends on threshold ($b \neq 0$). Fig. 3 shows three SROC curves derived from Eq. 4, all with $a=2$ but different values of b . Nonzero values of b give asymmetric curves. If $b > 0$, the curve initially rises less steeply than the symmetric curve (with $b=0$), but then it rises more steeply and crosses the symmetric curve to achieve relatively high values of TPR for high values of FPR. The SROC curves with $b < 0$ exhibit the opposite behavior—see, for example, the curve with $b=-0.5$ in Fig. 3.

Interestingly, as suggested by Fig. 3 and as shown by Moses et al.,^[11] the family of curves defined by a fixed value of a all pass through a common point, located on the

Fig. 2 Summary receiver operating characteristic with various values of a ($b = 0$)

Fig. 3 Summary receiver operating characteristic with various values of b ($a = 2$)

antidiagonal, where $\text{TPR} = 1 - \text{FPR}$, or sensitivity equals specificity. That point has coordinates

$$\text{TPR} = \frac{\exp(a/2)}{1 + \exp(a/2)} \quad (6)$$

and

$$\text{FPR} = \frac{1}{1 + \exp(a/2)} \quad (7)$$

Moses et al.^[11] denote the value of TPR at this point by Q^* . In ROC analysis, Q^* has been suggested as a further summary measure. It corresponds to the point closest to the ideal top-left corner of the SROC space in symmetric curves.

The fact that all SROC curves with a given value of a pass through the same Q^* point means that Q^* conveys no additional statistical information beyond the odds ratio. However, use of Q^* can be motivated by its simple interpretability, given that Q^* is the point on the SROC curve where $\text{TPR} = 1 - \text{FPR}$; thus it represents the diagnostic threshold at which the probability of a correct diagnosis is constant for all subjects. Also, as will be shown later, the existence of a common value of Q^* permits the derivation of a useful lower bound for AUC.

As a consequence of assuming model 3, when $b \neq 0$, the SROC curve has a region where $\text{TPR} < \text{FPR}$, which lies below the main diagonal. This region may be seen, for example, near the lower-left corner in the curve for $b=0.5$ in Fig. 3. In this region, the test would theoretically be performing worse than at random. However, in practice, this region is very small. Even if relatively strong heterogeneity (with $b > 0$) is present, the “improper” part of the SROC curve (where $\text{TPR} < \text{FPR}$) includes very low values of TPR, and these values correspond to test thresholds that are unlikely to be acceptable in clinical practice.

On the other hand, if heterogeneity with $b < 0$ occurs, the improper part of the curve corresponds to very high values of FPR, which would again have no clinical relevance. See Ref. [28] for numerical details of this effect.

We now briefly discuss the behavior of model 3 for extreme values of b . As $b \rightarrow 1$, the fitted SROC curve becomes progressively steeper, and in the limit case at $b = 1$ it degenerates to a vertical line. This could occur, for example, if there was no variation in FPR between studies. However, the line still passes through the common Q^* point defined by Eqs. 6 and 7. Once $b > 1$, the curve inverts and shows a negative relationship of TPR to FPR. This is implausible in practice, except perhaps by chance in small samples.

Similar behavior is seen if b is near or below -1 . Near $b = -1$, the curve is horizontal, indicating no relationship of TPR to FPR. This could occur if there was no variation in TPR between studies. If $b < -1$, the curve again inverts (to a different shape) and suggests an implausible negative relationship between TPR and FPR. Despite this, all the curves for $b > 1$ possess the common value of Q^* given by Eqs. 6 and 7. In practice, data yielding $b > 1$ are unlikely. Empirical experience suggests that practical meta-analysis data sets often have b close to 0, and are rarely larger than 0.5 in absolute value.

SUMMARY MEASURES: AREA UNDER THE CURVE AND Q

The AUC is a popular index of the overall performance of a test.^[5–7,19,20,29] As mentioned earlier, AUC ranges from 1 for a perfect test that always correctly diagnoses, to 0 for a test that never correctly diagnoses. In single studies, AUC can be interpreted as the probability that the test will correctly rank a randomly chosen case/noncase pair with respect to their test values.^[30] The AUC is intended to fulfill the same function in meta-analyses, and in effect one assumes that the SROC curve accurately conveys test performance at the individual subject level.

Although numerical integration is required in general to obtain AUC, some special cases are of interest because they yield exact analytic expressions and comparative results, as we now discuss. As expected, AUC increases with a , for fixed b . By examining Eq. (5), one can prove that for a given value of a , AUC is maximized when $b=0$, implying that AUC is optimally large in homogeneous studies.^[28] Furthermore, one may show that AUC is symmetric in b , so that negative values of b yield the same value of AUC as the equivalent positive value, this despite the very different shapes of their associated SROC curves. If $a=b=0$, then from Eq. (5) $\text{AUC} = \int_0^1 x dx = \frac{1}{2}$. By symmetry, it is evident that $\text{AUC} = 1/2$ when $a=0$ even if $b \neq 0$, so $\text{AUC} = 1/2$ indicates random overall performance for any set of studies.

In the homogeneous case $b=0$, the general expression 5 becomes

$$AUC = \int_0^1 \frac{\exp(a) \left(\frac{x}{1-x} \right)}{1 + \exp(a) \left(\frac{x}{1-x} \right)} dx$$

In this case, we can obtain an exact solution

$$AUC_{\text{hom}} = \frac{OR}{(OR-1)^2} [(OR-1) - \ln(OR)] \quad (8)$$

where AUC_{hom} indicates the AUC for homogeneous studies, and $OR = \exp(a)$. If $a=0$ (or $OR=1$), then the special value $AUC_{\text{hom}} = 1/2$ should be used in place of Eq. (8), which is then degenerate. Expression 8 can be used to evaluate AUC for homogeneous studies, without the need for numerical integration. As demonstrated later, expression 8 is also a useful upper bound and close approximation for AUC in heterogeneous studies. For reference, Table 1 shows the value of AUC, Q^* , and their difference for a range of values of OR in the homogeneous case.

By noting that AUC declines with increasing b , and that the limit curve with $b \rightarrow 1$ passes through the common Q^* point, from Eqs. (6) and (7), we may deduce that a lower bound for AUC in curves with a given value of a is

$$Q^* = \frac{\exp(a/2)}{1 + \exp(a/2)} = \frac{\sqrt{OR}}{1 + \sqrt{OR}} \quad (9)$$

which is equivalent to the TPR value given in Eq. (6). Also, Q^* from Eq. (9) and the maximum value AUC_{hom} from Eq. (8) provide easily computable lower and upper bounds, respectively, for AUC with any given value of $a > 0$.

Numerical Tabulations

Numerical evaluations of expressions 8 and 9 demonstrate that in the homogeneous case, the difference between AUC_{hom} and Q^* increases for moderate values of OR, but

Table 1 AUC_{hom} , Q^* , and Their Difference for Various Values of the Diagnostic Odds Ratio: Homogeneous Case

Odds ratio	AUC_{hom}	Q^*	$AUC_{\text{hom}} - Q^*$
0.5	0.386	0.414	-0.028
1	0.500	0.500	0.000
1.5	0.567	0.551	0.017
2	0.614	0.586	0.028
3	0.676	0.634	0.042
4	0.717	0.667	0.051
5	0.747	0.691	0.056
10	0.827	0.760	0.067
20	0.887	0.817	0.069
30	0.913	0.846	0.068
40	0.929	0.863	0.065
50	0.939	0.876	0.063

is never more than about 7%.^[28] The maximum difference occurs at $a=2.85$ (or $OR=17.3$), which value is the solution to a transcendental equation. For larger values of a , the difference declines very slowly, with a limit value $AUC_{\text{hom}} - Q^* = 0$ at $a = \infty$.

The numerical integration of Eq. (5) for the heterogeneous case allows one to assess the impact of heterogeneity on the value of AUC. For a fixed value of OR, AUC declines slowly as b increases from 0 (homogeneous studies) to larger values (increasing heterogeneity). However, the dependence of AUC on b is weak, and the dominant effect on AUC is the value of OR (or a). For $|b| < 0.4$, the percentage change in AUC compared to the homogeneous case is less than 2%. Accordingly, AUC_{hom} provides a good approximation to AUC even in heterogeneous studies.^[28]

STANDARD ERRORS OF AREA UNDER THE CURVE AND Q

We first consider the sample variation in $\widehat{AUC}$. From Eq. (5), we see that AUC is a function of the regression parameters a and b , and hence the variability in $\widehat{AUC}$ is a function of the sample variation in $\hat{a}$ and $\hat{b}$. Using the delta method, an approximate variance for $\widehat{AUC}$ is

$$\begin{aligned} \text{var}(\widehat{AUC}) = & \left(\frac{\partial AUC}{\partial a} \right)^2 \text{var}(\hat{a}) + \left(\frac{\partial AUC}{\partial b} \right)^2 \text{var}(\hat{b}) \\ & + 2 \left(\frac{\partial AUC}{\partial a} \right) \left(\frac{\partial AUC}{\partial b} \right) \text{cov}(\hat{a}, \hat{b}) \end{aligned} \quad (10)$$

where, from Eq. 5

$$\begin{aligned} \frac{\partial AUC}{\partial a} = & \left(\frac{1}{1-b} \right) \exp \left(\frac{a}{1-b} \right) \\ & \times \int_0^1 \frac{\left(\frac{x}{1-x} \right)^p}{\left[1 + \left(\frac{x}{1-x} \right)^p \exp \left(\frac{a}{1-b} \right) \right]^2} dx \end{aligned} \quad (11)$$

$$\begin{aligned} \frac{\partial AUC}{\partial b} = & \left(\frac{1}{1-b} \right)^2 \exp \left(\frac{a}{1-b} \right) \\ & \times \int_0^1 \frac{\left(\frac{x}{1-x} \right)^p \left[a + 2 \ln \left(\frac{x}{1-x} \right) \right]}{\left[1 + \left(\frac{x}{1-x} \right)^p \exp \left(\frac{a}{1-b} \right) \right]^2} dx \end{aligned} \quad (12)$$

and $p = (1+b)/(1-b)$. The variances and covariance of $\hat{a}$ and $\hat{b}$ can be directly obtained from the standard regression software used to fit model 3 to the data.

In general, evaluation of $\text{var}(\widehat{AUC})$ again requires numerical integration. However, for the special case of homogeneous studies where $b=0$, an approximate, large-sample

expression is possible. Using the delta method, we may then obtain

$$SE(\widehat{AUC}_{\text{hom}}) = \frac{OR}{(OR-1)^3} [(OR+1)\ln OR - 2(OR-1)] SE(\hat{a}) \quad (13)$$

Eq. 13 implies $SE(\widehat{AUC}_{\text{hom}})$ is symmetric in $\ln(OR)$, although we would usually be concerned with values $OR > 1$. When $OR=1$, expression 13 is degenerate, but by using L'Hôpital's rule, one can show that in the neighborhood of $OR=1$,

$$SE(\widehat{AUC}) \approx SE(\hat{a})/6 \quad (14)$$

The delta method also yields an approximate standard error for $\hat{Q}^*$ as

$$SE(\hat{Q}^*) = \frac{\sqrt{OR}}{2(\sqrt{OR} + 1)^2} SE(\hat{a}) \quad (15)$$

Moses et al.^[11] give this result in an alternative form involving $\cosh(a/4)$. Numerical evaluations show that the standard errors of Q^* and AUC are both maximized when $OR = 1$, so the least precise situation for either index is for tests that have close to random performance. In the region of $OR = 1$, $SE(\widehat{AUC}) \approx 1/6$ and $SE(\hat{Q}^*) \approx 1/8$. Comparisons show $SE(\widehat{AUC}) > SE(\hat{Q}^*)$ for OR values between 1 and 17.3, the same value associated with the values of AUC and Q^* ; for $OR > 17.3$, AUC has the smaller standard error. Both standard errors approach 0 as $a \rightarrow \infty$.

For heterogeneous studies, $SE(\widehat{AUC})$ is not necessarily maximized when $a = 0$, because it involves $\text{var}(\hat{b})$ and $\text{cov}(\hat{a}, \hat{b})$ as well as $\text{var}(\hat{a})$. However, it is the last of these terms that dominates, with the other two making relatively small numerical contributions. Thus in practice $SE(\widehat{AUC})$ is maximized approximately when $OR = 1$, even for heterogeneous studies. For most values of OR , the standard error declines by up to about 10% at the most extreme level of b .

OTHER ISSUES WITH THE FIXED-EFFECT MODEL

So far, we have established some basic properties of the SROC curve under model 3, and we found that the value AUC_{hom} associated with homogeneous studies is a reasonable upper-bound approximation even for the general AUC with heterogeneous studies. The corresponding standard error also provides a good approximation for heterogeneous studies, and is conservatively large except in some cases of extreme heterogeneity. In the presence of strong heterogeneity, the AUC would be an inadequate summary of the data anyway, and it would then be preferable to examine the SROC curve in more detail, including specific TPR values for given FPR.

Q^* also provides an easily computed lower bound for AUC, but empirically appears to be not quite as good an approximation as AUC_{hom} . The motivation for Q^* as an index in its own right is that it is located where the SROC curve crosses the antidiagonal from (0, 1) to (1, 0) of the SROC space. Hence $TPR = 1 - FPR$ at Q^* , and so the probability of an incorrect result from the test is the same for cases and noncases. Q^* is therefore a point of "indifference" between false-positive and false-negative diagnostic errors. In homogeneous studies, Q^* is the point on the SROC curve lying closest to the optimal upper-left corner, but this is not true with heterogeneous studies.

Use of Q^* as the summary measure assumes implicitly that false-negative and false-positive test results are of equal value. In practice, there may be different costs associated with these two types of error: One wishes to minimize false-positive results because of the additional testing required to establish the correct diagnosis (noncase), and because the additional tests tend to be more costly, invasive, or risky. On the other hand, false-negative results lead to disease cases being missed, with possible deterioration in their prognosis. In general, one must weigh the false-positive and false-negative errors to balance the overall performance of the test in a population; the optimal diagnostic threshold does not then correspond in general to the Q^* point.

One can motivate the use of AUC as an index that represents the probability that the test will correctly rank a case/noncase pair of subjects.^[15,30] It can also be thought of as the average TPR over the entire range of FPR values. Because it summarizes the whole SROC curve, AUC has a symmetric interpretation with respect to either TPR or FPR. The AUC is affected by the whole SROC curve, including regions with limited or no data, or by sectors corresponding to TPR and FPR values that are unlikely to occur in practice. Accordingly, it has been suggested that partial SROC curves be adopted, by limiting attention to those portions of the SROC curve of clinical interest, or where data are actually observed.^[31-34]

There are some unresolved issues on the use of partial SROC curves and the corresponding partial AUC^[35] First, the partial AUC may be thought of as the average TPR within a restricted range of FPR, but not vice versa. Hence the partial AUC has an asymmetric interpretation with respect to TPR and FPR; on the other hand, the complete AUC enjoys a symmetric interpretation with respect to both types of test error. Second, there may be some arbitrariness in which regions of the curve to select. One might examine the SROC curve within a prespecified range of TPR values, for instance by defining a maximum acceptable level for clinical practice. Another approach would be to choose the region according to the observed range of data in the meta-analysis; the choice itself would then be affected by sampling variation, which might be substantial in meta-analyses involving small studies. Furthermore, a reasonable choice for one test may be unreasonable for another test, thus complicating their comparison.

The analytic methods for AUC presented in this paper can be extended to cover the partial AUC and its standard error.^[35] We may expect the effect of interstudy heterogeneity to be greater for the partial AUC than the weak effect seen for the full AUC. For instance, if attention is limited to values of FPR < 0.2 when $a=2$ (Fig. 3), the corresponding partial AUC will be greater when $b > 0$ than when $b < 0$. Hence the partial AUC lacks symmetry with respect to b . On the other hand, the complete AUC has some compensating decreases in contributions to the area at higher values of FPR, so there are only modest changes in the total AUC as b varies (Fig. 3). We may also recall that AUC is symmetric with respect to b , so that the same summary value will be obtained for a given strength of dependence of diagnostic accuracy on the test threshold. The partial AUC does not possess these properties, and hence it will show greater dependence on the degree of interstudy heterogeneity. Further work is needed to explore the properties of the partial AUC in more detail. Similar investigation is needed for other summary indices, such as the ASC (Area Swept out by the Curve), PLC (Projected Length of the Curve),^[36,37] and the Gini/Lorenz coefficients.^[38]

Sampling variability and dependence between test accuracy and test threshold are unlikely to fully account for the observed heterogeneity in test accuracy between studies. Additional sources of heterogeneity can be explored by examining the association between test accuracy and study level covariate information.^[3,9,39] However, given the limited data on patient and study design characteristics that are typically available, it is unlikely that study level variables will fully explain the “excess” variability in test accuracy.^[27] Inappropriately assuming a fixed effect can lead to spurious precision and result in covariates being incorrectly identified as significantly associated with test accuracy.^[27] A mixed model that includes random effects for test accuracy can take into account unexplained variability between studies. This approach is used in the hierarchical (mixed) models outlined briefly below, which, unlike the Moses approach, directly models the TPR and FPR for each study.

HIERARCHICAL (MIXED) EFFECTS MODELS

Rutter and Gatsonis Model

An alternative approach to fitting SROC curves has been proposed by Rutter and Gatsonis.^[21,22] As with the Moses model, each study (i) contributes an estimate of TPR and FPR to the meta-analysis. For each study, the number in the diseased group who have a positive test result (y_{i1}) and the number in the nondiseased group who have a positive test result (y_{i2}) are both assumed to follow a binomial distribution such that $y_{ij} \sim \beta(n_{ij}, \pi_{ij})$, where π_{ij} represents the probability of a positive test for group j ($j=1,2$) in study i , and n_{ij} represents the total number of positive and

negative test results in group j . The model is based on an ordinal logistic regression model^[40] and takes the form $\text{logit}(\pi_{ij}) = (\theta_i + \alpha_i \text{dis}_{ij}) \exp(-\beta \text{dis}_{ij})$ where dis_{ij} represents the true disease status (coded as -0.5 for the nondiseased and 0.5 for the diseased). The model parameters estimate a proxy for threshold (θ_i) that gives a positive test result in study i and the diagnostic accuracy (α_i) for study i . The parameter β allows for an association between test accuracy and test threshold. The estimated SROC is symmetric when $\beta=0$. This hierarchical (multilevel) model takes into account both the within- and between-study variability.

The within-study variability is modeled at the first level. For the i th study, $\text{logit}(\text{TPR}_i)$ and $\text{logit}(\text{FPR}_i)$ are modeled to estimate the threshold (θ_i) and diagnostic accuracy (α_i) for that study. Hence random effects are assumed for both threshold and accuracy as these may vary across studies. When the SROC is symmetric (i.e., $\beta=0$), the level 1 analysis for each study reduces to an ordinary logistic regression model where α_i is estimated by $\text{logit}(\text{TPR}_i) - \text{logit}(\text{FPR}_i)$ (which is equivalent to the observed value D_i in study i for the dependent variable in model 3) and θ_i is estimated by $(\text{logit}(\text{TPR}_i) + \text{logit}(\text{FPR}_i))/2$ (which is equivalent to $S_i/2$, where S_i is the observed value in study i for the independent variable in model 3). The sampling variability for both TPR_i and FPR_i is taken into account.

The variability between studies is modeled at level 2. The random effects for test threshold and accuracy are assumed to be independent (uncorrelated) and normally distributed with $\theta_i \sim N(\Theta, \tau_\theta^2)$ and $\alpha_i \sim N(\Lambda, \tau_\alpha^2)$. The hyperparameters Θ and Λ represent the expected threshold and accuracy, respectively, across all studies in the analysis. If $\tau_\theta^2 = 0$ and $\tau_\alpha^2 = 0$, the model reduces to a fixed-effect model. Because each study contributes only one point in ROC space to the analysis, a single study does not provide information on the shape of the SROC. Hence the shape parameter (β) is assumed to be a fixed effect, which is estimated from the study points jointly considered. The hierarchical model may be fitted using Markov Chain Monte Carlo (MCMC) Bayesian methods.^[21,22] This requires a third level to specify prior distributions for all model parameters.

A summary ROC curve can be constructed by choosing a range of values of FPR and using the estimated model parameters to compute the predicted values for sensitivity. The expected TPR at a chosen FPR value is given by $\text{TPR}(\text{FPR}) = 1 / (1 + \exp[-\{\Lambda \exp(-0.5\beta) + \text{logit}(\text{FPR}) \exp(-\beta)\}])$.

The expected operating point on the curve is estimated using $E(\text{TPR}) = 1 / (1 + \exp[-\{(\Theta + \Lambda/2) \exp(-\beta/2)\}])$ and $E(\text{FPR}) = 1 / (1 + \exp[-\{(\Theta - \Lambda/2) \exp(-\beta/2)\}])$. Covariates can be added to the model to assess whether threshold, accuracy, and/or the shape of the SROC vary with patient or study characteristics. Such terms are generally fitted as fixed effects, but could also be included as random effects.

Rutter and Gatsonis demonstrate how their model may be fitted using Markov Chain Monte Carlo (MCMC) methods.^[22] A more straightforward approach that utilizes

PROC NLMIXED in SAS has been shown to provide very similar results.^[41,42] PROC NLMIXED allows for a non-linear function of the model parameters, and for a non-normal error distribution, but the random effects are restricted to be normally distributed. Summary estimates of TPR, FPR, likelihood ratios can be computed and their asymptotic confidence intervals estimated using the delta method.^[42] The distribution of the random effects may be checked by examining a histogram and normal probability plot of their Empirical Bayes (EB) estimates. This follows the same approach adopted for checking distributional assumptions for linear mixed models.^[43,44]

Bivariate Model

A bivariate model has been proposed that, like the Rutter and Gatsonis model, assumes the number correctly diagnosed (y_{ij}) for both the diseased ($j = 1$) and non-diseased ($j = 2$) groups follow a binomial distribution $B(\pi_{ij}, n_{ij})$, where π_{ij} and n_{ij} are defined as above. The random effects distribution for $\text{logit}(\text{TPR}_i)$ is assumed to follow a normal distribution with mean μ_A and variance σ_A^2 , and the random effects distribution for $\text{logit}(1-\text{FPR}_i)$ is assumed to follow a normal distribution with mean μ_B and variance σ_B^2 . Correlation between sensitivity and specificity is assumed, and estimated as σ_{AB} .^[45] The parametrization of this model allows for straightforward estimation of the expected (summary) operating point for the test which is given by exponentiating μ_A and μ_B . A 95% confidence region for this summary point can also be derived from the model estimates. The model may also be fitted using PROC NLMIXED,^[46] or using other software that can fit generalized linear mixed models.

It has been demonstrated that the Rutter and Gatsonis model and the bivariate model are equivalent when no covariates are included.^[47] Hence, the parameter estimates from either of the two models can be used to estimate the underlying summary ROC curve and the estimated operating point. However, the addition of covariates to the Rutter and Gatsonis model allows inferences to be made readily about how the position and shape of the underlying summary ROC curve varies with study and patient characteristics, whereas the addition of covariates to the bivariate model allows inferences to be made readily about how the expected sensitivity and specificity vary with study and patient characteristics.

ADVANTAGES OF THE HIERARCHICAL MODELS

The hierarchical models described above provide a general framework for the meta-analysis of diagnostic test performance. The straightforward linear regression method proposed by Moses does not directly model the TPR and FPR values for each study.^[11] Hence, because D and S are functions of both TPR and FPR, the parameters for the

Moses model cannot be used to obtain the expected operating point on the SROC, the corresponding likelihood ratios at that point, or the standard errors of these estimates. The hierarchical models do not have this limitation, and also have the advantage that they take account of both the within- and between-study variability, thereby taking account of unexplained variability in diagnostic test performance between studies through the inclusion of random effects.

CONCLUSION

The hierarchical models provide a rigorous method of analysis that takes proper account of the sources of variability in test performance between studies. The resulting standard errors (and confidence intervals) reflect the unexplained heterogeneity that is likely to be present in many diagnostic meta-analyses. The hierarchical models also allow estimation of clinically relevant indicators of test performance such as the expected TPR, FPR and likelihood ratios. A range of alternative fixed-effect and random effects methods are available for obtaining these summary measures.^[23] However, they can lead to results that are potentially inconsistent within the same meta-analysis. For instance, for the same data, summary estimates of TPR and FPR could be computed that are not consistent with summary estimates of likelihood ratios or an SROC estimated using the Moses model. A useful feature of the hierarchical models is that fixed effect approaches can be regarded as special cases. Recent work has demonstrated that the parameters from the bivariate model can be used to generate alternative SROC curves that include not only the Rutter and Gatsonis SROC curve but also the random effects equivalent of the Moses SROC curve.^[48]

The Moses fixed-effect SROC model has the advantage of simplicity, and it makes no assumptions about the distribution of S . It is useful as a preliminary step before fitting a hierarchical model. Major differences in the variables found to be associated with test accuracy or the shape of the SROC would warrant investigation as this may be indicative of convergence problems or model instability.

An issue that potentially affects all of the methods discussed here is that reference test (or gold standard) has been assumed to be error-free. In fact, the reference standard is often itself subject to measurement error, as illustrated, for example, in the observable differences between pathologists and radiologists in their assessments of the same sample material. Several methods have been proposed to correct for referent errors, but they primarily pertain to data from single studies. Rather little has been done on this problem in the context of combining studies in a meta-analysis, but one proposed approach has been to use a latent class framework to extend the logit-threshold model (Eq. [3]), and to recognize the fact that both the candidate and referent tests are potentially subject to error.^[49]

The true disease state of an individual cannot be directly observed, but an estimate of the probability of an individual having disease can be obtained from the latent class model. This then permits a deattenuation of the errors in the data, and the resulting adjustment to the SROC curve tends to lead to an improved estimate of test performance.

Further development of the SROC methods is required to allow comparison of summary curves when not all component studies in a meta-analysis are independent of one another. For example, if the purpose of a meta-analysis is to compare the diagnostic performance of alternative tests some of the component studies may make direct comparisons of two tests while other studies only evaluate one. Methods to take such dependencies into account have been proposed for therapeutic studies,^[50] and extensions to diagnostic test comparisons would be useful.

The techniques discussed here apply to situations where only summary measures (TPR and FPR) from each study are available. Sometimes access to the individual level data in each study is possible, in which case a multilevel analysis, taking both inter- and intrastudy variation into account, as well as the effects of subject-specific covariates would be feasible. However, in practice, most diagnostic meta-analyses must rely on published data where the reporting of methodology and patient characteristics is often poor.^[1,39,51,52] The reporting of diagnostic studies is likely to improve in the future because of new standards of reporting that have been adopted by many journals.^[53] Accordingly, further work to understand the properties of the SROC curve based on summary data from each study seems warranted.

University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.

Abstract

In practice, the shelf-life of a frozen drug product is usually determined based on a two-phase stability study. This entry examines statistical models and procedures for two-phase stability analysis and presents an example concerning the establishment of a shelf-life statement for a frozen drug product.

INTRODUCTION

For every drug product in the marketplace, the Food and Drug Administration (FDA) requires that an expiration dating period be indicated on the immediate container label. The expiration dating period is also known as shelf-life. The shelf-life of a drug product is defined as the time interval in which the characteristic of the drug product (e.g., potency) remains within an approved specification after being manufactured. The shelf-life of a drug product is usually established through a stability study under the appropriate storage conditions. (See, e.g., FDA,^[1] International Conference on Harmonization [ICH],^[2] Chow,^[3] Chow and Liu,^[4] and Chow and Shao.^[5]) However, some drug products must be stored at certain temperatures, such as -20°C (frozen temperature), 5°C (refrigerator temperature), and 25°C (room temperature), in order to maintain their stability until use.^[6] Drug products of this kind are referred to as *frozen drug products*. Unlike the usual drug products, a shelf-life statement for frozen drug products is usually composed of multiple phases with different storage temperatures. For example, a commonly adopted shelf-life statement for frozen products could be *24 months at -20°C followed by 2 weeks at 5°C* .

In practice, the shelf-life of a frozen drug product is usually determined based on a two-phase stability study. The first phase of the stability study is intended to determine the drug's shelf-life under a frozen storage condition, while the second phase of the stability study is intended to estimate the shelf-life of the drug product under a refrigerated condition. The first phase of the stability study is usually referred to as the *frozen study*, while the second phase of the stability study is known as the *thawed study*. The frozen study is usually conducted in a similar manner to a regular long-term stability study, except that the drug is stored in frozen conditions. In other words, stability testing will be normally conducted at 3-month intervals during the first year, 6-month intervals during the second year, and

annually thereafter. Stability testing for the thawed study is conducted following the stability testing for the frozen study. It may be performed at 1-week (or 1-day) intervals, for up to several weeks.

Mellon^[6] suggested that stability data from the frozen study and a thawed study be analyzed separately to obtain a combined shelf-life for the drug product. However, his method does not account for the fact that the stability at the second phase (thawed study) may depend upon the stability at the first phase (frozen study), i.e., an estimated shelf-life from a thawed study following 3 months of frozen storage may be longer than that of one following 6 months of frozen storage. Shao and Chow^[7] proposed a method for the determination of drug shelf-lives for the two phases using a two-phase linear regression based on the statistical principle described in both the FDA and ICH stability guidelines.^[1,2]

In the section “Statistical Models,” statistical models and procedures for two-phase stability analysis are described. An example concerning the establishment of a shelf-life statement for a frozen drug product is given in the section “An Example.” A brief discussion is given in the section “Conclusion.”

STATISTICAL MODEL

Without loss of generality, we consider the case where the drug characteristic decreases with time. The other case where the drug characteristic increases with time can be treated similarly. For continuous assay results (e.g., potency expressed in percent of label claim), the following linear model is usually considered to describe the degradation of a drug product in stability analysis:

$$y_{ij} = \beta'_i x_{ij} + e_{ij}, i = 1, \dots, k, j = 1, \dots, n$$

where i is the index for batch, x_{ij} is a $p \times 1$ vector of non-random covariates of the form $(1, t_{ij}, w_{ij})'$, $(1, t_{ij}, t_{ij} w_{ij})'$ or

$(1, t_{ij}, w_{ij}, t_{ij} w_{ij})'$ is the j th time point for the i th batch, w_{ij} is the j th value of a vector of nonrandom covariates (e.g., package type and strength), β_i is an unknown $p \times 1$ vector of parameters, and e_{ij} 's are independent random errors (in observing y_{ij} 's), which are assumed to be identically distributed as $N(0, \sigma_e^2)$.

When $\beta_i = \beta$ for all i , we state that there is no batch-to-batch variation. In such a case, the above model reduces to a fixed effects linear regression model. When β_i 's are dissimilar, the best way to interpret the batch-to-batch variation is to consider $\beta_i, i = 1, \dots, k$, as a random *sample* from a population of all future batches, which the established shelf-life is to be applied. In this entry, we assume that β_i 's are independent and identically distributed as $N(\beta, \Sigma)$, where β and Σ are the unknown mean vector and covariance matrix of β_i , respectively. Consequently, the above model becomes a mixed effects linear regression model. The fixed effects linear regression model is a special case of the general mixed effects model. It should be noted that the statistical procedures employed in these two cases may be different (see, e.g., Ref. [5]).

Two-Phase Regression Analysis

For simplicity and the purpose of illustration, we assume that the time interval is the only covariate and that there is no batch-to-batch variation. Results for general situations can be similarly obtained.

For the first phase of the stability study, we have data

$$y_{ij} = \alpha + \beta t_j + e_{ij}, \quad i = 1, \dots, k, \quad j = 1, \dots, n$$

where y_{ij} is the assay result from the i th batch at time t_j , α , and β are unknown parameters, and e_{ij} 's are independent random errors that are identically distributed as $N(0, \sigma_e^2)$. Because there is no batch-to-batch variation, α and β do not depend on i . Hence data from different batches at each time point can be treated as replicates.

At time t_j second-phase stability data are collected at time intervals $t_{jh}, h = 1, \dots, m \geq 2$. The total number of data for the second phase is knm . Data from the two phases are independent. Typically, $t_{jh} = t_j + s_h$, where s_h is time in the second phase and $s_h = 1, 2, 3$ days (or weeks), etc.

Because the degradation lines for the two phases intersect, the intercept of the second-phase degradation line at time t is $\alpha + \beta t$. Let $\gamma(t)$ be the slope of the second-phase degradation line at time t . Then, at time t_j , we have second-phase stability data

$$y_{ijh} = \alpha + \beta t_j + \gamma(t_j) s_h + e_{ijh}, \quad i = 1, \dots, k, \quad h = 1, \dots, m$$

where $j = 1, \dots, n$ and e_{ijh} 's are independent random errors identically distributed as $N(0, \sigma_{e2}^2)$.

It is assumed that $\gamma(t)$ is a polynomial in t with unknown coefficients, i.e.,

$$\gamma(t) = \sum_{l=0}^L \gamma_l t^l$$

where γ_l 's are unknown parameters and $L + 1 < km$ and $L < n$. Typically, $L \leq 2$. When $L = 0, \gamma(t) = \gamma_0$ is a common slope model. When $L = 1, \gamma(t) = \gamma_0 + \gamma_1 t$ is a linear trend model, while when $L = 2, \gamma(t) = \gamma_0 + \gamma_1 t + \gamma_2 t^2$ is a quadratic trend model.

The Second-Phase Shelf-Life

The first-phase shelf-life can be estimated based on the first-phase data $\{y_{ij}\}$ and the method as described in the FDA stability guideline. We now consider the second-phase shelf-life. Because the slope of the second-phase degradation line may vary with t , we estimate the slope at time t_j using the second-phase data at t_j .

$$b_j = \frac{\sum_{i=1}^k \sum_{h=1}^m (s_h - \bar{s}) y_{ijh}}{k \sum_{h=1}^m (s_h - \bar{s})^2}$$

where $\bar{s}$ is the average of s_h 's. Because $L < n$, the unknown parameters γ_l can be estimated by the least squares estimators under the following model:

$$b_j = \sum_{l=0}^L \gamma_l t_j^l + \text{error}$$

i.e., the parameter vector $(\gamma_0, \gamma_1, \dots, \gamma_L)'$ can be estimated by

$$(W'W)^{-1}W'b$$

where $b = (b_1, \dots, b_n)'$, $W' = [g(t_1), \dots, g(t_n)]$, and $g(t) = (1, t, \dots, t^L)'$. Consequently, the slope $\gamma(t)$ can be estimated by

$$\hat{\gamma}(t) = g(t)'(W'W)^{-1}W'b$$

The covariance matrix of $(W'W)^{-1}W'b$ is

$$V = \frac{\sigma_{e2}^2}{k \sum_{h=1}^m (s_h - \bar{s})^2} (W'W)^{-1}$$

where the unknown variance σ_{e2}^2 can be estimated by

$$\hat{\sigma}_{e2}^2 = \frac{1}{knm - n(L+2)} \sum_{i=1}^k \sum_{j=1}^n \sum_{h=1}^m (y_{ijh} - \bar{y}_j - b_i(s_h - \bar{s}))^2$$

and $\bar{y}_j$ is the average of y_{ijh} 's with a fixed j . Let be the same as $\hat{V}$ but with σ_{e2}^2 replaced by $\hat{\sigma}_{e2}^2$. Then $(W'W)^{-1}W'b$ and its estimated covariance matrix $\hat{V}$ can be used to form approximate t -tests.

The variance of $\hat{\gamma}(t)$ can be estimated by $g(t)' \hat{V}g(t)$. For fixed i and s , let

$$v(t, s) = v(t) + g(t)' \hat{V}g(t)s^2$$

and

$$L(t, s) = \hat{\alpha} + \hat{\beta}t + \hat{\gamma}(t)s - t_{0.95; kn+knm-2-n(L+2)} \sqrt{V(t, s)}$$

where $\hat{\alpha}$ and $\hat{\beta}$ are the least square estimators of α and β based on the data from the first phase. For any fixed t less than the first-phase true shelf-life, i.e., t satisfying $\alpha + \beta t > \eta$, the second-phase shelf-life can be estimated as

$$\hat{s}^*(t) = \inf \{s \geq 0 : L(t, s) \leq \eta\}$$

(if $L(t, s) < \eta$ for all s , then $\hat{s}^*(t) = 0$), where η is the given lower limit for the drug characteristic. That is, if the drug product is taken out of the first-phase storage condition at time t , then the estimated second-phase shelf-life is $\hat{s}^*(t)$. The justification for $\hat{s}^*(t)$ is that for any t satisfying $\alpha + \beta t > \eta$,

$$P\{\hat{s}^*(t) \leq \text{the true second phase shelf life}\} \approx 95\%$$

for large sample sizes or small error variances.

In practice, the time at which the drug product is taken out of the first-phase storage condition may be unknown. In such a case, we may apply the following method to assess the second-phase shelf-life. Select a set of time intervals $t_v < \hat{t}^*$, $v = 1, \dots, J$, where $\hat{t}^*$ is the estimated first-phase shelf-life, and construct a table (or a figure) for $(t_v, \hat{s}^*(t_v))$, $v = 1, \dots, J$ (see, for example, Table 1). If a drug product is taken out of the first-phase storage condition at time t_0 , which is between t_v and t_{v+1} , then its second-phase shelf-life is $\hat{s}^*(t_{v+1})$.

AN EXAMPLE

A pharmaceutical company wishes to establish a shelf-life for a drug product at a frozen condition of -20°C followed by a shelf-life at a refrigerated condition of 5°C . During the frozen phase, the product stored at -20°C was tested at 0, 3, 6, 9, 12, and 18 months. At each sampling time point of the frozen phase, the product was tested at 1, 2, 3, and 5 weeks at the refrigerated condition of 5°C . Three batches of the drug product were used at each sampling time point ($k = 3$). Assay results in the percent of labeled concentration (g/50 ml) are given in Table 1. The p -values from the F -tests of batch-to-batch variation for the two phases of data are larger than 0.25, and, thus, we combined three batches in the analysis.

Assay results in Table 1 indicate that the degradation of the drug product at the refrigerated phase is faster at later sampling time points of the frozen phase. Assuming the linear trend model $\gamma(t) = \gamma_0 + \gamma_1 t$, we obtain estimates

Table 1 Stability Data

Time		Stability data	
t (mo)	s (day)	Frozen condition	Refrigerated condition
0		100.0, 100.1, 100.1	
3		99.2, 99.0, 99.1

	35		91.7, 91.8, 91.4
6		98.2, 98.2, 98.1	
	7		96.7, 96.5, 96.7
	14		95.4, 95.2, 95.1
	21		93.6, 93.5, 93.6
	35		90.3, 90.6, 90.5
9		97.5, 97.4, 97.5	
	7		95.9, 95.6, 95.7
	14		94.5, 94.3, 94.1
	21		92.7, 92.5, 92.5
	35		89.3, 89.5, 89.3
12		96.4, 96.5, 96.5	
	7		94.5, 94.7, 94.8
	14		92.8, 93.3, 93.4
	21		91.3, 91.4, 91.5
	35		88.2, 88.2, 87.9
18		94.4, 94.6, 94.5	
	7		92.6, 92.6, 92.4
	14		91.0, 91.1, 90.6
	21		88.9, 89.0, 89.0
	35		85.1, 85.6, 85.6

$\hat{\gamma}_0 = -0.2025$ and $\hat{\gamma}_1 = -0.0031$ with estimated standard errors of 0.0037 and 0.0004, respectively. Hence the hypothesis that $\gamma_1 = 0$ (which leads to the common slope model $\gamma(t) = \gamma_0$) is rejected based on an approximate t -test with the significance level ≤ 0.0001 .

Table 2 lists the lower confidence bounds $L(t)$ and $L(t, s)$ and the second-phase data. For the purpose of comparison, the results are given under both common slope and linear trend models. The acceptable lower product specification limit in this example is $\eta = 90$. Thus the first-phase (frozen) shelf-life for this drug product is 32 months.

The results for $L(t, s)$ in Table 2 are given at s such that $L(t, s) > 90$ whereas $L(t, s+1) < 90$. Thus s values listed in Table 2 are the second-phase (refrigerated) shelf-lives for various t values. For example, if the drug product is taken out of the frozen storage condition at month 10, then its refrigerated shelf-life is 29 days under the common slope model or 28 days under the linear trend model.

If we are unable to determine which of the two models (common slope and linear trend) is significantly better than

Table 2 Lower Confidence Bounds and Estimated Shelf-Lives

33	89.98	—	—	—	—

the other, then we could adopt a conservative approach by selecting the shorter of the shelf-lives computed under the two models. Note that a higher-degree polynomial model does not always produce shorter shelf-lives at the second phase. In the example, the linear trend model produced shorter second-phase shelf-lives in later months, but longer second-phase shelf-lives in early months. This is because under the common slope model, the estimated common slope is the average of the five estimated slopes (in different months) that decrease with time (*t*), because $\hat{\gamma}_1 < 0$.

CONCLUSION

In practice, the assumption of simple linear regression in the second phase of a stability study may not be appropriate. For example, there may be an acceleration in decay with *s* in the second phase. The method described in this entry can be easily extended to the case where polynomial regression models are considered in the second phase. For example, suppose that in the second phase,

$$y_{ijh} = \alpha + \beta t_j + \gamma(t_j)s_h + \rho(t_j)s_h^2 + e_{ijh}$$

where both $\gamma(t)$ and $\rho(t)$ are polynomials, At month t_j , let b_j and c_j be the least squares estimates of the coefficients of the linear and quadratic terms in the second-phase quadratic model. Then, the estimators of $\gamma(t)$ and $\rho(t)$ can be obtained using

$$b_j = \gamma(t_j) + \text{error}$$

and

$$c_j = \rho(t_j) + \text{error}$$

Usual model diagnostic methods may be applied to select an adequate model.

The selection of sampling lime points at the second-phase stability study depends on how fast the degradation would be. It may be a good idea to have shorter time intervals for the second phase in later months; for example, we may test the drug product more frequently in later weeks. For a fixed total sample size, it is of interest to examine the relative efficiency for the estimation of shelf-lives using either more sampling time points in the first phase and less sampling time points in the second phase or less sampling time points in the first phase and more sampling time points in the second phase. The allocation of sampling lime points at each phase then becomes an interesting research topic for two-phase shelf-life estimation. Furthermore, because the degradation at the second phase is highly correlated with the degradation at the first phase, it may be of interest to examine such correlation for future design planning.

For the method described in this article, equal assay variabilities for the second-phase data at different t_j are assumed. If this assumption is not true, the variance estimator should be modified.^[8] Note that the method described in this entry can be extended to the case of multiple-phase shelf-life estimation in a straight forward manner.

Stability Matrix Designs

Earl Nordbrock

Nordbrock Consulting, Draper, Utah, U.S.A.

Abstract

For a new drug product, accelerated testing is required for 6 months, and long-term testing is required for the length of shelf life; thus the cost of the stability studies can be substantial. This leads quite naturally to statistically designed stability studies, which are called matrix designs. This entry provides several models of stability matrix designs and discusses the general rules when using each model.

Keywords: Matrix design; Stability matrix; Time design.

INTRODUCTION

Stability studies are conducted “to provide evidence on how the quality of a drug substance or drug product varies with time under the influence of a variety of environmental factors such as temperature, humidity, and light, and to establish a retest period for the drug substance or a shelf life for the drug product and recommended storage conditions.”^[1] Because a drug product is defined as the dosage form in the final package, stability studies must be applicable to all strengths and all packages. For a new drug product, accelerated testing is required for 6 months, and long-term testing is required for the length of shelf life; thus the cost of the stability studies can be substantial. This leads quite naturally to statistically designed stability studies, which are called *matrix* designs, or studies where “a selected subset of the total number of possible samples for all factor combinations is tested at a specified time point.”^[1]

HISTORY

Statistically designed stability studies were first used in the early 1980s (E. Nordbrock, 1981, stability protocols) and were accepted by the U.S. Food and Drug Administration (FDA) (W. Fairweather, 1982, personal communication). In 1989, Nordbrock^[2] and Wright^[3] made presentations to stability groups at two different conferences. Nakagaki,^[4] who was present at the first of these conferences, made a presentation using the terminologies *matrix* and *bracket*. Nordbrock^[5] made a presentation in 1991, and the first journal articles appeared in 1992.^[6–8] Since then, there have been a number of presentations and publications in this area.^[9–28]

A guidance on bracketing and matrixing was issued in 2003.^[29] A guidance on evaluation of stability data was issued in 2004.^[30]

DESIGNS

Background

Because the basic analysis applied to stability data is a linear regression of the parameter of interest on time, the selection of observations that give the minimum variance for the slope is to take one-half at the beginning of the study and one-half at the end. Thus statistically designed stability designs attempt to use this basic principle while being cognizant of the fact that there is a well-defined beginning (start of the stability study, usually called $t - 0$) but not a single end, because analyses are typically done at several different times (e.g., at the time a registration application for the new drug product is filed, or yearly for a marketed product). Because analyses are done at multiple times, there is no unique best design, and the choice of design must use the fact that analyses will be done after additional data are collected. Several designs are given next. These designs, presented via examples, can easily be applied to other studies.

Basic Matrix 2/3 on Time Design

A complete long-term study for one strength of a dosage form in one package has three batches, with all three tested every 3 months in the first year, every 6 months in the second year, and annually thereafter (see the entry on *Expiration Dating Period*). Thus if a 36-month shelf life is desired and the complete study is used, each of the three batches is tested at 0, 3, 6, 9, 12, 18, 24, and 36 months. The basic matrix 2/3 on time design has only two of the three batches tested at intermediate time points (other than time 0 and 36), as presented in [Table 1](#). If an analysis is to be done after 18 months (e.g., for a registration application), the basic matrix 2/3 on time design can be modified by testing all batches at 18 months.

Table 1 Basic Matrix 2/3 on Time Design

Batch	Test times
A	0, 3, 9, 12, 24, 36
B	0, 3, 6, 12, 18, 36
C	0, 6, 9, 18, 24, 36

Table 2 Matrix 2/3 on Time Design with Multiple Packages

Batch	Pkg 1	Pkg 2	Pkg 3
A	T1	T2	T3
B	T2	T3	T1
C	T3	T1	T2

Pkg 1 = Package 1, etc.

Table 3 Test Code Definitions

Code	Test times after time 0
T1	3, 9, 12, 24, 36
T2	3, 6, 12, 18, 36
T3	6, 9, 18, 24, 36

Batches are tested at time 0, consistent with the manufacturing process.

Matrix 2/3 on Time Design with Multiple Packages

The first extension of the basic design is when one strength is packaged into three packages (i.e., when each batch is packaged into each of three packages). The basic matrix 2/3 on time design is applied to each package in a balanced fashion, as presented in Tables 2 and 3. Balance means that each batch is tested twice at each intermediate time point, and each package is tested twice at each intermediate time point. If an analysis will be done after 18 months (e.g., for a registration application), this design can be modified by testing all batch-by-package combinations at 18 months.

Matrix 2/3 on Time Design with Multiple Packages and Multiple Strengths

The next extension is when three strengths (say, 10, 20, and 30) are manufactured using different weights of the same formulation, giving nine subbatches. It is further assumed that there are three packages for each strength. In this case, the basic matrix 2/3 on time design can be applied to each of the nine subbatches in a balanced fashion, as presented in Tables 4 and 5. Balance in this design means that each subbatch is tested twice at each intermediate time point, each package is tested twice at each intermediate time point for each batch, each batch is tested six times at each intermediate time point, and each package is tested six times at each intermediate time point. If an analysis will be done after 18 months (e.g., for a registration application), this design can be modified by testing all batch-by-strength-by-package combinations at 18 months.

Table 4 Matrix 2/3 on Time Design with Multiple Packages and Multiple Strengths

Batch	Strength	Pkg 1	Pkg 2	Pkg 3
A	10	T1	T2	T3
A	20	T2	T3	T1
A	30	T3	T1	T2
B	10	T2	T3	T1
B	20	T3	T1	T2
B	30	T1	T2	T3
C	10	T3	T1	T2
C	20	T1	T2	T3
C	30	T2	T3	T1

Pkg 1 = Package 1, etc.

Table 5 Test Code Definitions

Code	Test times after time 0
T1	3, 9, 12, 24, 36
T2	3, 6, 12, 18, 36
T3	6, 9, 18, 24, 36

Strength subbatches are tested at time 0, consistent with the manufacturing process.

Matrix 1/3 on Time Design

A further reduction in the amount of testing is accomplished by reducing the testing in each of the preceding designs from 2/3 to 1/3. For example, the basic 1/3 on time design has one of the three batches tested at each intermediate time point, as presented in Table 6. If an analysis will be done after 18 months (e.g., for a registration application), the basic matrix 1/3 on time design can be modified by testing all batches at 18 months.

Matrix on Batch $\times$ Strength $\times$ Package Combinations

If there are multiple strengths and multiple packages, one could also choose to test only a portion of the batch-by-strength-by-package combinations. An example of when this might be appropriate is when there are three batches, each made into two strengths, giving six subbatches. Although three packages will be used, the batch size is small and only two packages can be manufactured in each strength subbatch. A matrix design on batch $\times$ strength $\times$ package combinations is presented in Tables 7 and 8, with two packages selected for each of the six subbatches, and where time is also matrixed by the factor 1/2. This design is approximately balanced because two packages are tested per subbatch, one or two strengths are tested for each selected package by batch, four subbatches are tested for each package, etc. Similar statements for the balance on time can be made.

Table 6 Basic Matrix 1/3 on Time Design

Batch	Test times
A	0, 3, 12, 36
B	0, 6, 18, 36
C	0, 9, 24, 36

Table 7 Matrix 1/2 on Time and Matrix on Batch $\times$ Strength $\times$ Package

Batch	Strength	Pkg 1	Pkg 2	Pkg 3
A	10	T1	T2	–
A	20	T2	–	T1
B	10	T2	–	T1
B	20	–	T1	T2
C	10	–	T1	T2
C	20	T1	T2	–

Table 8 Test Code Definitions

Code	Test times after time 0
T1	3, 9, 18, 36
T2	6, 12, 24, 36

Strength subbatches are tested at time 0, consistent with the manufacturing process.

Uniform Matrix Design

Another approach to design is the uniform matrix design,^[16] for which “the same time protocol is used for all combinations of the other design factors.” The strategy is to delete certain times (e.g., the 3-month, 6-month, 9-month, and 18-month time points); therefore testing is done only at 12, 24, and 36 months. This design has the advantages of simplifying the data entry of the study design and eliminating time points that add little to reducing the variability of the slope of the regression line. The disadvantage is that if there are major problems with the stability, there is no early warning because early testing is not done. Further, it may not be possible to determine if the linear model is appropriate (e.g., it may not be possible to determine whether there is an immediate decrease followed by very little decrease). However, the major disadvantage is that this design is probably not acceptable to some regulatory agencies.

ANALYSIS

Background

Although there may be instances when a linear regression is not appropriate, the rest of this discussion assumes that a straight-line linear regression of the parameter

of interest on time is appropriate. Further, it is assumed that the parameter of interest is expected to decrease over time. For long-term data with a single package and a single strength, the ICH Q1E Guidance^[30] specifies that the 95% one-sided lower confidence bound for the mean regression line must be above the lower specification at all times prior to the shelf life. When there are multiple strengths and/or multiple packages, according to ICH Q1E^[30] there are three possible approaches for analysis. The first approach is to analyze each package-by-strength combination separately—in other words, to do multiple analyses. The second approach is to model all data with one analysis, with separate intercepts and separate slopes for each batch by strength by package, without testing for poolability, so there is no reduced model. The third approach is to model all data with one analysis and test for poolability and then select the appropriate reduced model.

SEPARATE ANALYSIS APPROACH

In the first approach, multiple analyses are conducted, with a separate analysis of each package-by-strength-by-batch. A shelf life is calculated for each of the separate analyses, and the product shelf life is the minimum of all the package-by-strength-by-batch shelf lives.

One Analysis Approach, without Testing Poolability

In the second approach, one analysis is done which includes all data. A shelf life is estimated using individual intercepts, individual slopes, and the pooled mean square error from the entire data set. Shelf life for each batch-by-package-by-strength is taken as the time the batch-by-package-by-strength remains within acceptable limits, i.e., the time that the 95% one-sided lower confidence bound for the mean regression line remains above specification.

If there are multiple batches but only one package and one strength, the SAS model is $Y = B A B^*A$, where B is a class term for batch and A is the covariate for age. The 95% one-sided lower confidence bound for the mean regression line is calculated for each batch. The shelf life of each batch is such that the confidence bound is within the specification at all times prior to the shelf life. The shelf life of the product is the minimum of the batch shelf lives.

If there are multiple batches and multiple packages but only one strength, and if the initials for a particular batch are applicable to all packages, then the SAS model is $Y = B A B^*A P^*A B^*P^*A$, where B is a class term for batch, P is a class term for package and A is the covariate for age. This model has separate slopes for each batch-by-package, separate intercepts for each batch, and a common intercept for all packages from the same batch. For example, if initials are tested using bulk product (before the product is packaged), and all packages are entered

into the study at the same time, then this model is typically appropriate. The 95% one-sided lower confidence bound for the mean regression line is calculated for each batch by package. The shelf life of each batch-by-package is such that the confidence bound is within the specification at all times prior to the shelf life. The shelf life of the product is the minimum of all batch-by-package shelf lives.

One Analysis: Testing Poolability

When using the model-building (test poolability) approach, it is very important that the full model reflect the manufacturing process. In this section, it is assumed that there are multiple strengths and multiple packages and that a batch is manufactured into multiple strengths by using different weights of the same exact formulation. It is assumed that a granulation batch is split into subbatches, where each subbatch is manufactured into a different-strength product using different weights of the granulation, and it is assumed that every strength is manufactured from every granulation batch. It is assumed that the time 0 samples are collected from each tablet subbatch, and every tablet subbatch is packaged into all packages.

The full model includes slope terms for all two-way interactions of package, strength, and batch, and it includes intercept terms that reflect the manufacturing process. The manufacturing process dictates that each tablet subbatch must have a separate intercept in the full model, but there is no need to allow packages in each tablet subbatch to have separate intercepts. (Process validation provides evidence that the entire tablet subbatch is uniform.)

Thus in the example, the full SAS model is: $Y = B \ S \ B*S \ A \ B*A \ P*A \ S*A \ B*P*A \ B*S*A \ P*S*A$ with B as a class term for granulation batch, P as a class term for package, S as a class term for strength, and A as a covariate for time. The model building begins by testing the slope two-way interactions to determine if any can be deleted, using a significance level of 0.25 when the batch is part of the term and 0.05 otherwise. Then the main-effect slope terms are tested, using the 0.25 (batch) or 0.05 (not batch) level. Terms that are not significant are deleted, except that any main-effect slope included in a nondeleted two-way slope term cannot be deleted.

After deleting slope terms, the intercept terms are tested (using the same criterion for significance as was used for slopes) and nonsignificant terms are deleted. Using the final model, the 95% one-sided lower confidence bound for the mean regression line(s) is (are) found, and shelf life is assigned for each package-by-strength combination such that the 95% one-sided lower confidence bound(s) is (are) within specification at all times prior to the shelf life.

Slightly different algorithms for deleting terms from the full model have been proposed.^[14,27] A correction to Ref. [27] is planned.^[28]

COMPARISON OF DESIGNS

Nordbrock^[6] compared designs based on the power approach. This approach computes the probability that a statistical test will be significant when there is a specified alternative slope configuration. Power can be computed easily in SAS.^[23] The strategy is to compute power for several designs and then to choose the design that has acceptable power and the smallest sample size (or cost). Acceptable power is not well defined at this stage. Note that in Ref. [2] the power of specific $1 - df$ contrasts were calculated using a $1 - df(t)$ test, whereas in Ref. [23] the power of specific contrasts is computed using the corresponding F -test from the analysis of variance.

Other methods of comparing designs are given in Ju and Chow,^[18] where the criterion is the precision for estimating shelf life. Murphy^[16] gives five criteria for comparing designs, based on moments, D -efficiency, uncertainty, G -efficiency, and power.

When evaluating designs, it is also important to answer the question "What is the probability of being able to defend the desired shelf life with the study?"^[23] In other words (assuming that the parameter is expected to decrease over time), what is the probability that the 95% one-sided lower confidence bound for the slope will be acceptable for specified values of the slope(s) for particular subsets of data, which may include, for example, only one strength and/or only one package? It is important to know at the design stage what the statistical penalty (with respect to shelf life) might be if differences among packages and/or strengths are found. Similarly, Nordbrock^[26] compares matrix designs to full designs using the probability of achieving the desired shelf life.

FACTORS ACCEPTABLE TO MATRIX

In the foregoing, examples have been used to present possible matrix designs. In this section, a summary of when it is acceptable to matrix is given based on a document prepared by the PhRMA Stability Working Group,^[20] on FDA presentations;^[21,22] and on ICH Q1D.^[29]

- It is acceptable to matrix at all stages of development for a drug product and also for a drug substance. It is acceptable for new drug application (NDA) studies, investigational new drug application (IND) studies, supplements, and marketed product studies.
- It is acceptable to matrix for all types of products, such as solids, semisolids, liquids, and aerosols.
- It is acceptable to matrix after bracketing.
- It is acceptable to matrix when there are multiple sources of raw material (e.g., drug product).
- It is acceptable to matrix if there are multiple sites of drug product manufacture.
- It is acceptable to matrix when identical formulations are manufactured into several strengths.

- It is acceptable to matrix if formulations are closely related (e.g., difference in colorant or flavoring).
- Matrixing is applicable to the orientation of container during storage.
- Matrixing may be acceptable in certain cases when closely related formulations are used for different strengths (e.g., if an inactive is replaced by an active).
- Matrix across container and closure systems may be applicable if justified.
- It is acceptable to matrix within a package composition type, e.g., of different sizes if fill (i.e., head space) is the same, or if of the same size but different fills (head space). It may be acceptable to matrix if container size and fill size change, if there is adequate explanation. It is not acceptable to matrix across package composition type (e.g., blisters and HDPE).
- It is not acceptable to matrix across storage conditions. However, it is acceptable to do a separate matrix design for each storage condition.
- It is not acceptable to matrix across parameters, such as dissolution and potency. However, it is acceptable to do a separate design for each parameter.
- Matrixing is applicable regardless of method precision; however, it should be remembered that when using a matrix design, the resulting shelf life is generally shorter than when a complete design is used and that when the method precision is larger, the difference between a complete design and a matrixed design will be larger (i.e., a larger penalty to the sponsor, resulting in a shorter shelf life for the matrix design than the complete design).
- Matrixing is applicable regardless of the stability of the product. However, comments similar to those in the preceding point apply, and it should be remembered that if a product has a poor stability profile (e.g., shelf life of 1 year), matrixing will usually result in an even shorter shelf life.
- The latest guideline should be consulted for applicability.

GENERAL RULES

Several general rules should be followed when designing studies:

- Matrix designs should be approximately balanced (i.e., for all one-way, two-way combinations of batch, package, and strength that are ever tested, approximately the same number of tests should be done cumulatively to every time point).
- When every batch-by-strength-by-package combination is not tested, every strength-by-package combination that is ever tested should be tested in at least two batches (i.e., for every package-by-strength combination that is ever tested, there should be at least two batches tested; W. Fairweather, 1995, personal communication).

- Unless there are manufacturing restrictions such as in the foregoing example, it is probably acceptable to matrix on batch $\times$ strength $\times$ package combinations only when there are more than three strengths or more than three packages.

CONCLUSION

Matrix designs are generally applicable to many situations and can result in significant savings, with the 1/3 matrix on time readily acceptable for stable products. There are two basic approaches when analyzing data from a matrixed design. There are several methods used to evaluate and to compare potential designs.

Abstract

Genetic mapping with molecular markers provides a powerful tool for identifying the genes underlying a complex trait. Molecular markers are distinctive segments of DNA that serve as landmarks for a target gene. This entry examines genetic mapping in terms of statistical genetics.

GENETIC MAPPING

Most traits in nature and of fundamental importance to agriculture, biology, and health sciences are complex in terms of their genetic underpinnings. First, these traits are usually controlled by a network of genes that act independently or interactively although an exact pattern of genetic action is never known. Second, the expression of the genes involved depends on the genetic background of an organism, the stage of its development, and the environment in which the organism is reared. Because of these characteristics, classic Mendelian genetic approaches have been little useful for studying the genetic architecture of complex traits.

Genetic mapping with molecular markers provides a powerful tool for identifying the genes underlying a complex trait. Molecular markers are distinctive segments of DNA that serve as landmarks for a target gene. Markers are genetically linked to the target gene on a chromosome, so that through linkage analysis the latter can be inferred from the former. With the availability of high-throughput molecular markers almost for any genome, the genetic analysis of complex traits has entered a new era in which genes that control a complex trait can be located individually on the genome and their genetic effects can be estimated. The motive force that allows the identification of individual genes for complex traits, or quantitative trait loci (QTLs), comes from Lander and Botstein^[1] for interval mapping of QTLs.

Because QTLs cannot be observed directly, Lander and Botstein constructed a mixture model-based likelihood, in which each individual is assumed to arise from one of all possible QTL genotypes. The likelihood is then solved by implementing the expectation-maximization

(EM) algorithm. The existence of significant QTLs can be tested and their genetic effects on a complex trait estimated. The past 20 years have witnessed a resurgence of interest in the development of statistical models and algorithms for genetic mapping of complex traits. Broadly speaking, these new methods have the following aims, among others: improving the precision of QTL separation from a chromosomal segment (composite interval mapping);^[2,3] extending genetic mapping to accommodating dominant markers;^[4] outbred crosses;^[5] complicated mating designs;^[6] and natural populations;^[7] mapping multiple interacting QTLs (multiple interval mapping);^[8] mapping QTLs for trait correlations^[9] and genotype-environment interactions;^[10] mapping QTLs for binary^[11] and categorical traits;^[12] and deriving QTL mapping procedures within the Bayesian paradigm.^[13,14] Specific statistical issues for QTL mapping have also been considered in several areas including the determination of critical thresholds,^[15,16] model selection,^[17] non-parametric mapping of QTLs,^[18] and asymptotic properties of QTL parameter estimates.^[19]

These statistical mapping models have played an important role in the characterization of the genetic architecture of complex traits. Thousands of thousands of QTLs have been reported in plants, animals, and humans. In several examples, the detection of QTLs by genetic mapping leads to the positional cloning of genes for quantitative traits, such as grain yield and its components in agriculture,^[20] life-history traits in evolutionary biology,^[21] and diseases in humans.^[22] As a statistical approach, the theory and methods for genetic mapping have continued to grow steadily. Especially, integrated with biological problems and genomic technologies, this approach is seeking new motive forces and expected to produce new breakthroughs.

FUNCTIONAL MAPPING

The integration of genetic mapping with growth and developmental processes leads to the birth of functional mapping. Many biological processes in real life are expected to arise as curves, such as growth curves, allometric scalings, hormone profiles, and norms of reaction. A growth curve or trajectory represents an individual as a function that relates the age of an individual to some measure of its size. Because ages can be considered as continuous, growth trajectories can be thought of as function-valued traits^[23,24] or infinite-dimensional characters.^[25] Other examples of function-valued traits include the continuous change of a morphological or physiological variable with body size (allometric scaling)^[26,27] and responsive phenotypes of a given genotype to a changing environment (reaction norm).^[28] The common property of these function-valued traits is that they can be described as a function (or stochastic process) of some independent and continuous variable consisting of an infinite number of points, such as age, temperature, light intensity, or biological size.

To determine the dynamic changes of genetic effects in development, one can measure trait values at a series of discrete time points or states and then extend the traditional interval mapping approach to accommodate the multivariate nature of time-dependent traits. However, this extension is limited in three aspects:

- i. Individual expected means of different QTL genotypes at all points and all elements in the covariance matrix need to be estimated, resulting in substantial computational difficulties when the vector and matrix dimensions are large;
- ii. The result from this approach may not be biologically meaningful because the underlying biological principle for growth is not incorporated;
- iii. This approach cannot be well deployed in a practical scheme because of (ii). Thus, some biologically interesting questions cannot be asked and answered.

More recently, a library of statistical methods implemented with growth model theories have been proposed to map QTL that govern growth trajectories using molecular linkage maps.^[29–34] The basic principle of this method, called functional mapping, is to express the genotypic means of a QTL at different time points in terms of a continuous growth function with respect to time t . Under this principle, the parameters describing the shape of growth curves, rather than the genotypic means as expected in traditional mapping strategies, are estimated within a maximum likelihood framework. Also unlike traditional mapping strategies, functional mapping estimates the parameters that model the structure of the covariance matrix among multiple different time points and, therefore, largely reduces the number of parameters being estimated for variances and

covariances, especially when the number of time points is large.

Although the idea of functional mapping was originally stimulated from a growth model for a controlled cross, this method has been extensively expanded to a wide spectrum of biomedical and evolutionary fields. Wang and Wu^[35] and Wang et al.^[36] combined the principle of functional mapping and mathematical models for HIV dynamics established by Ho et al.^[37] to map host QTL that govern dynamic changes of HIV viral loads in a human body. Functional mapping has been extended to study the genetic control of drug response^[38] by implementing well-developed pharmacodynamic and pharmacokinetic models.^[39] “Naturally occurring” or “programmed” cell death (PCD) in which the cell uses specialized cellular machinery to kill itself is a ubiquitous phenomenon that occurs early in organ development. A recently extended functional-mapping model has made it possible to identify and detect QTL that are responsible for PCD in any organism.^[40]

In theory, genetic information contained within any kind of longitudinally measured data can be extracted by functional mapping. The advantages of functional mapping in model flexibility, stability, and power result from its statistical formulation including the mathematical approximation of the mean vector and the modeling of the covariance structure by stationary^[29] or non-stationary models.^[41] Although original functional mapping was derived for the biological processes that can be described by parametric functions, functional mapping has been modified within the nonparametric context to accommodate the situation in which biologically meaningful mathematical equations do not exist.^[40] Analysis of longitudinal data needs a number of mathematical manipulations for the covariance matrix, such as the calculation of the matrix determinant and inverse. In modeling the structure of covariance matrix by parametric functions, however, these mathematical manipulations will not be made possible because of the matrix's sparse structure, especially when the dimension of the matrix is too large. To overcome this problem, Zhao and Wu^[42] have proposed a denoising approach based on wavelet transformation to reduce the dimensionality of longitudinal data. Preserving the favorable properties of functional mapping, wavelet thresholding approach creates a new direction in statistical genetics to manipulate high-dimensional multivariate dynamic data in both statistically and biologically meaningful ways.

FROM QTL TO QTN

Although QTL mapping has proven to be powerful for study the genetic control of complex traits at the molecular level, QTLs identified on the basis of one or a set of known polymorphic markers by this approach actually represent chromosomal segments in which the structure and organization of DNA sequences are unknown. A more accurate

and useful approach for the characterization of genetic variants contributing to quantitative variation is to directly analyze DNA sequences associated with a particular disease.^[43] DNA sequence variations between individuals are responsible for our biological and physical differences. Although approximately 99.9% of human DNA sequences are the same across a population, the remaining 0.1% variations in these sequences can have a major impact on how humans respond to disease, bacteria, viruses, toxins, chemicals, and drugs.^[44–46]

Many of these DNA sequence variants lie outside genes and may have no effect on the individual. Some of the variations lie within genes, so they may alter the structure of the proteins that are encoded by these genes and thus may affect the functioning of these proteins. Some variants may lie within the region responsible for regulating the expression of the gene and thus may alter the level of gene expression, the specific timing, or the location of expression.

SINGLE NUCLEOTIDE POLYMORPHISMS

Single nucleotide polymorphisms or SNPs (pronounced “snips”) are single base pair positions in genomic DNA sequence at which a single nucleotide (A, T, C, or G) in the genome differs, so different alleles exist, between members of a species (or between paired chromosomes

in an individual). For example, two DNA sequences on the same chromosome segment from two different individuals, AGCCT and AGCTT, contain a difference in a single nucleotide (C to T). In this case, we say that there are two alleles: C and T. Almost all common SNPs have only two alleles. The specific set of alleles observed on a single chromosome, or part of a chromosome, is called a haplotype. In Fig. 1, four DNA sequences of the same chromosome region from four different persons are compared. Most of the DNA sequence is identical; only three bases have variation, which are called single nucleotide polymorphisms or SNPs (Fig. 1a). By taking out the SNPs from original DNA sequence, a particular combination of bases at nearby SNPs can be constructed, which is called haplotype (Fig. 1b). SNPs are the most frequent form of sequence variation among individuals, accounting for around 90% of sequence differences.^[47] The rest may due to insertions or deletions, repeats, and rearrangements. These SNPs are present at high density in the genome, highly conserved and also evolutionarily stable making them powerful tools for the mapping and diagnosis of disease related alleles. SNPs are of great value for biomedical research and for developing pharmaceutical products or medical diagnostics.

SNP alleles that are closely located tend to be inherited together. This leads to associations between these alleles in the population, called linkage disequilibrium (LD). Many empirical studies found highly significant
